1 Scope

Chapel is a new parallel programming language that is under development at Cray Inc. in the context of the DARPA High Productivity Computing Systems initiative.

This document is ultimately intended to be the definitive specification of the Chapel language. The current draft is a work-in-progress and therefore incomplete.
2 Notation

Special notations are used in this specification to denote Chapel code and to denote Chapel syntax.

Chapel code is represented with a fixed-width font where keywords are bold and comments are italicized.

Example.

```
for i in D do // iterate over domain D
    writeln(i); // output indices in D
```

Chapel syntax is represented with standard syntax notation in which productions define the syntax of the language. A production is defined in terms of non-terminal (italicized) and terminal (non-italicized) symbols. The complete syntax defines all of the non-terminal symbols in terms of one another and terminal symbols.

A definition of a non-terminal symbol is a multi-line construct. The first line shows the name of the non-terminal that is being defined followed by a colon. The next lines before an empty line define the alternative productions to define the non-terminal.

Example. The production

```
bool-literal:
    true
    false
```

defines `bool-literal` to be either the symbol `true` or `false`.

In the event that a single line of a definition needs to break across multiple lines of text, more indentation is used to indicate that it is a continuation of the same alternative production.

As a short-hand for cases where there are many alternatives that define one symbol, the first line of the definition of the non-terminal may be followed by “one of” to indicate that the single line in the production defines alternatives for each symbol.

Example. The production

```
unary-operator: one of
    +  - ˜  !
```

is equivalent to

```
unary-operator:
    +
    -
    ˜
    !
```
As a short-hand to indicate an optional symbol in the definition of a production, the subscript “opt” is suffixed to the symbol.

*Example.* The production

```
formal:
  formal-tag identifier formal-type\_opt default-expression\_opt
```

is equivalent to

```
formal:
  formal-tag identifier formal-type default-expression
  formal-tag identifier formal-type
  formal-tag identifier default-expression
  formal-tag identifier
```
3 Organization

This specification is organized as follows:

- Chapter 1, Scope, describes the scope of this specification.
- Chapter 2, Notation, introduces the notation that is used throughout this specification.
- Chapter 3, Organization, describes the contents of each of the chapters within this specification.
- Chapter 4, Acknowledgements, offers a note of thanks to people and projects.
- Chapter 5, Language Overview, describes Chapel at a high level.
- Chapter 6, Lexical Structure, describes the lexical components of Chapel.
- Chapter 7, Types, describes the types in Chapel and defines the primitive and enumerated types.
- Chapter 8, Variables, describes variables and constants in Chapel.
- Chapter 9, Conversions, describes the legal implicit and explicit conversions allowed between values of different types. Chapel does not allow for user-defined conversions.
- Chapter 10, Expressions, describes the non-parallel expressions in Chapel.
- Chapter 11, Statements, describes the non-parallel statements in Chapel.
- Chapter 12, Modules, describes modules in Chapel. Chapel modules allow for name space management.
- Chapter 13, Functions, describes functions and function resolution in Chapel.
- Chapter 14, Tuples, describes tuples in Chapel.
- Chapter 15, Classes, describes reference classes in Chapel.
- Chapter 16, Records, describes records or value classes in Chapel.
- Chapter 17, Unions, describes unions in Chapel.
- Chapter 18, Ranges, describes ranges in Chapel.
- Chapter 19, Domains, describes domains in Chapel. Chapel domains are first-class index sets that support the description of iteration spaces, array sizes and shapes, and sets of indices.
- Chapter 20, Arrays, describes arrays in Chapel. Chapel arrays are more general than in most languages including support for multidimensional, sparse, associative, and unstructured arrays.
- Chapter 21, Iterators, describes iterator functions.
- Chapter 22, Generics, describes Chapel’s support for generic functions and types.
- Chapter 23, Input and Output, describes support for input and output in Chapel, including file input and output.
- Chapter 24, Task Parallelism and Synchronization, describes task-parallel expressions and statements in Chapel as well as synchronization constructs, atomic variables, and the atomic statement.
Organization

- Chapter 25, Data Parallelism, describes data-parallel expressions and statements in Chapel including reductions and scans, whole array assignment, and promotion.

- Chapter 26, Locales, describes constructs for managing locality and executing Chapel programs on distributed-memory systems.

- Chapter 27, Domain Maps, describes Chapel’s domain map construct for defining the layout of domains and arrays within a single locale and/or the distribution of domains and arrays across multiple locales.

- Chapter 28, User-Defined Reductions and Scans, describes how Chapel programmers can define their own reduction and scan operators.

- Chapter 29, Memory Consistency Model, describes Chapel’s rules for ordering the reads and writes performed by a program’s tasks.

- Chapter 30 describes Chapel’s interoperability features for combining Chapel programs with code written in different languages.

- Appendix A, Collected Lexical and Syntax Productions, contains the syntax productions listed throughout this specification in both alphabetical and depth-first order.
4 Acknowledgments

The following people have been actively involved in the recent evolution of the Chapel language and its specification: Kyle Brady, Bradford Chamberlain, Sung-Eun Choi, Lydia Duncan, Michael Ferguson, Ben Harshbarger, Tom Hildebrandt, David Iten, Vassily Litvinov, Tom MacDonald, Michael Noakes, Elliot Ronaghan, Greg Titus, Thomas Van Doren, and Tim Zakian.

The following people have contributed to previous versions of the language and its specification: Robert Bocchino, David Callahan, Steven Deitz, Roxana Diaconescu, James Dinan, Samuel Figueroa, Shannon Hoffswell, Mary Beth Hribar, Mark James, Mackale Joyner, Jacob Nelson, John Plevyak, Lee Prokowich, Albert Sidelnik, Andy Stone, Wayne Wong, and Hans Zima.

We are also grateful to our many enthusiastic and vocal users for helping us continually improve the quality of the Chapel language and compiler.

Chapel is a derivative of a number of parallel and distributed languages and takes ideas directly from them, especially the MTA extensions of C, HPF, and ZPL.

Chapel also takes many serial programming ideas from many other programming languages, especially C#, C++, Java, Fortran, and Ada.

The preparation of this specification was made easier and the final result greatly improved because of the good work that went into the creation of other language standards and specifications, in particular the specifications of C# and C.
5 Language Overview

Chapel is an emerging parallel programming language designed for productive scalable computing. Chapel’s primary goal is to make parallel programming far more productive, from multicore desktops and laptops to commodity clusters and the cloud to high-end supercomputers. Chapel’s design and development are being led by Cray Inc. in collaboration with academia, computing centers, and industry.

Chapel is being developed in an open-source manner at GitHub under the Apache v2.0 license and also makes use of other third-party open-source packages under their own licenses. Chapel emerged from Cray’s entry in the DARPA-led High Productivity Computing Systems program (HPCS). It is currently being hardened from that initial prototype to more of a product-grade implementation.

This section provides a brief overview of the Chapel language by discussing first the guiding principles behind the design of the language and second how to get started with Chapel.

5.1 Guiding Principles

The following four principles guided the design of Chapel:

1. General parallel programming
2. Locality-aware programming
3. Object-oriented programming
4. Generic programming

The first two principles were motivated by a desire to support general, performance-oriented parallel programming through high-level abstractions. The second two principles were motivated by a desire to narrow the gulf between high-performance parallel programming languages and mainstream programming and scripting languages.

5.1.1 General Parallel Programming

First and foremost, Chapel is designed to support general parallel programming through the use of high-level language abstractions. Chapel supports a global-view programming model that raises the level of abstraction in expressing both data and control flow as compared to parallel programming models currently in use. A global-view programming model is best defined in terms of global-view data structures and a global view of control.

Global-view data structures are arrays and other data aggregates whose sizes and indices are expressed globally even though their implementations may distribute them across the locales of a parallel system. A locale is an abstraction of a unit of uniform memory access on a target architecture. That is, within a locale all threads exhibit similar access times to any specific memory address. For example, a locale in a commodity cluster could be defined to be a single core of a processor, a multicore processor, or an SMP node of multiple processors.
Such a global view of data contrasts with most parallel languages which tend to require users to partition distributed
data aggregates into per-processor chunks either manually or using language abstractions. As a simple example,
consider creating a 0-based vector with \( n \) elements distributed between \( p \) locales. A language that supports global-
view data structures, as Chapel does, allows the user to declare the array to contain \( n \) elements and to refer to the array
using the indices \( 0 \ldots n-1 \). In contrast, most traditional approaches require the user to declare the array as \( p \) chunks
of \( n/p \) elements each and to specify and manage inter-processor communication and synchronization explicitly (and
the details can be messy if \( p \) does not divide \( n \) evenly). Moreover, the chunks are typically accessed using local indices
on each processor (e.g., \( 0..n/p \)), requiring the user to explicitly translate between logical indices and those used by the
implementation.

A *global view of control* means that a user’s program commences execution with a single logical thread of control
and then introduces additional parallelism through the use of certain language concepts. All parallelism in Chapel
is implemented via multithreading, though these threads are created via high-level language concepts and managed
by the compiler and runtime rather than through explicit fork/join-style programming. An impact of this approach
is that Chapel can express parallelism that is more general than the Single Program, Multiple Data (SPMD) model
that today’s most common parallel programming approaches use. Chapel’s general support for parallelism does not
preclude users from coding in an SPMD style if they wish.

Supporting general parallel programming also means targeting a broad range of parallel architectures. Chapel is de-
gigned to target a wide spectrum of HPC hardware including clusters of commodity processors and SMPs; vector,
multithreading, and multicore processors; custom vendor architectures; distributed-memory, shared-memory, and shared
address-space architectures; and networks of any topology. Our portability goal is to have any legal Chapel program
run correctly on all of these architectures, and for Chapel programs that express parallelism in an architecturally-
neutral way to perform reasonably on all of them. Naturally, Chapel programmers can tune their code to more closely
match a particular machine’s characteristics.

### 5.1.2 Locality-Aware Programming

A second principle in Chapel is to allow the user to optionally and incrementally specify where data and computation
should be placed on the physical machine. Such control over program locality is essential to achieve scalable perfor-
mance on distributed-memory architectures. Such control contrasts with shared-memory programming models which
present the user with a simple flat memory model. It also contrasts with SPMD-based programming models in which
such details are explicitly specified by the programmer on a process-by-process basis via the multiple cooperating
program instances.

### 5.1.3 Object-Oriented Programming

A third principle in Chapel is support for object-oriented programming. Object-oriented programming has been in-
strumental in raising productivity in the mainstream programming community due to its encapsulation of related data
and functions within a single software component, its support for specialization and reuse, and its use as a clean mech-
nism for defining and implementing interfaces. Chapel supports objects in order to make these benefits available in
a parallel language setting, and to provide a familiar coding paradigm for members of the mainstream programming
community. Chapel supports traditional reference-based classes as well as value classes that are assigned and passed
by value.
5.1.4 Generic Programming

Chapel’s fourth principle is support for generic programming and polymorphism. These features allow code to be written in a style that is generic across types, making it applicable to variables of multiple types, sizes, and precisions. The goal of these features is to support exploratory programming as in popular interpreted and scripting languages, and to support code reuse by allowing algorithms to be expressed without explicitly replicating them for each possible type. This flexibility at the source level is implemented by having the compiler create versions of the code for each required type signature rather than by relying on dynamic typing which would result in unacceptable runtime overheads for the HPC community.

5.2 Getting Started

A Chapel version of the standard “hello, world” computation is as follows:

```chapel
writeln("hello, world");
```

This complete Chapel program contains a single line of code that makes a call to the standard `writeln` function.

In general, Chapel programs define code using one or more named modules, each of which supports top-level initialization code that is invoked the first time the module is used. Programs also define a single entry point via a function named `main`. To facilitate exploratory programming, Chapel allows programmers to define modules using files rather than an explicit module declaration and to omit the program entry point when the program only has a single user module.

Chapel code is stored in files with the extension `.chpl`. Assuming the “hello, world” program is stored in a file called `hello.chpl`, it would define a single user module, `hello`, whose name is taken from the filename. Since the file defines a module, the top-level code in the file defines the module’s initialization code. And since the program is composed of the single `hello` module, the `main` function is omitted. Thus, when the program is executed, the single `hello` module will be initialized by executing its top-level code thus invoking the call to the `writeln` function. Modules are described in more detail in §12.

To compile and run the “hello world” program, execute the following commands at the system prompt:

```
> chpl hello.chpl
> ./a.out
```

The following output will be printed to the console:

```console
hello, world
```
6 Lexical Structure

This section describes the lexical components of Chapel programs. The purpose of lexical analysis is to separate the raw input stream into a sequence of tokens suitable for input to the parser.

6.1 Comments

Two forms of comments are supported. All text following the consecutive characters // and before the end of the line is in a comment. All text following the consecutive characters /* and before the consecutive characters */ is in a comment. A comment delimited by /* and */ can be nested in another comment delimited by /* and */.

Comments, including the characters that delimit them, do not affect the behavior of the program (except in delimiting tokens). If the delimiters that start the comments appear within a string literal, they do not start a comment but rather are part of the string literal.

Example. The following program makes use of both forms of comment:

```chapel
/*
 * main function
 */
proc main() {
  writeln("hello, world"); // output greeting with new line
}
```

6.2 White Space

White-space characters are spaces, tabs, line feeds, form feeds, and carriage returns. Along with comments, they delimit tokens, but are otherwise ignored.

6.3 Case Sensitivity

Chapel is a case sensitive language.

Example. The following identifiers are considered distinct: chapel, Chapel, and CHAPEL.

6.4 Tokens

Tokens include identifiers, keywords, literals, operators, and punctuation.
6.4.1 Identifiers

An identifier in Chapel is a sequence of characters that starts with a lowercase or uppercase letter or an underscore and is optionally followed by a sequence of lowercase or uppercase letters, digits, underscores, and dollar-signs. Identifiers are designated by the following syntax:

\[
\text{identifier:} \quad \text{letter-or-underscore legal-identifier-chars opt}
\]

\[
\text{legal-identifier-chars:} \quad \text{legal-identifier-char legal-identifier-chars opt}
\]

\[
\text{legal-identifier-char:} \quad \text{letter-or-underscore digit $}
\]

\[
\text{letter-or-underscore:} \quad \text{letter -}
\]

\[
\text{letter: one of } \quad \text{A B C D E F G H I J K L M N O P Q R S T U V W X Y Z}
\]

\[
\text{a b c d e f g h i j k l m n o p q r s t u v w x y z}
\]

\[
\text{digit: one of } \quad 0 1 2 3 4 5 6 7 8 9
\]

Rationale. Why include “$” in the language? The inclusion of the $ character is meant to assist programmers using sync and single variables by supporting a convention (a $ at the end of such variables) in order to help write properly synchronized code. It is felt that marking such variables is useful since using such variables could result in deadlocks.

Example. The following are legal identifiers: Cray1, syncvar$, legalIdentifier, and legal_identifier.

6.4.2 Keywords

The following identifiers are reserved as keywords:

<table>
<thead>
<tr>
<th>_</th>
<th>dmapped</th>
<th>inout</th>
<th>private</th>
<th>subdomain</th>
</tr>
</thead>
<tbody>
<tr>
<td>align</td>
<td>do</td>
<td>iter</td>
<td>proc</td>
<td>sync</td>
</tr>
<tr>
<td>atomic</td>
<td>domain</td>
<td>label</td>
<td>public</td>
<td>then</td>
</tr>
<tr>
<td>begin</td>
<td>else</td>
<td>let</td>
<td>record</td>
<td>type</td>
</tr>
<tr>
<td>break</td>
<td>enum</td>
<td>local</td>
<td>reduce</td>
<td>union</td>
</tr>
<tr>
<td>by</td>
<td>export</td>
<td>module</td>
<td>ref</td>
<td>use</td>
</tr>
<tr>
<td>class</td>
<td>extern</td>
<td>new</td>
<td>return</td>
<td>var</td>
</tr>
<tr>
<td>cbegin</td>
<td>for</td>
<td>nil</td>
<td>scan</td>
<td>when</td>
</tr>
<tr>
<td>coforall</td>
<td>forall</td>
<td>noinit</td>
<td>select</td>
<td>where</td>
</tr>
<tr>
<td>config</td>
<td>if</td>
<td>on</td>
<td>serial</td>
<td>while</td>
</tr>
<tr>
<td>const</td>
<td>in</td>
<td>otherwise</td>
<td>single</td>
<td>yield</td>
</tr>
<tr>
<td>continue</td>
<td>index</td>
<td>out</td>
<td>sparse</td>
<td>zip</td>
</tr>
<tr>
<td>delete</td>
<td>inline</td>
<td>param</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
The following identifiers are keywords reserved for future use:

lambda

6.4.3 Literals

Bool literals are designated by the following syntax:

\[ \text{bool–literal: one of } \text{true } \text{false} \]

Signed and unsigned integer literals are designated by the following syntax:

\[ \text{integer–literal: } \text{digits } \]
\[ \text{0x hexadecimal–digits } \]
\[ \text{0X hexadecimal–digits } \]
\[ \text{0o octal–digits } \]
\[ \text{0O octal–digits } \]
\[ \text{0b binary–digits } \]
\[ \text{0B binary–digits } \]
\[ \text{digits: } \text{digit } \]
\[ \text{digit digits } \]
\[ \text{hexadecimal–digits: } \text{hexadecimal–digit } \]
\[ \text{hexadecimal–digit hexadecimal–digits } \]
\[ \text{hexadecimal–digit: one of } 0 1 2 3 4 5 6 7 8 9 A B C D E F a b c d e f \]
\[ \text{octal–digits: } \text{octal–digit } \]
\[ \text{octal–digit octal–digits } \]
\[ \text{octal–digit: one of } 0 1 2 3 4 5 6 7 \]
\[ \text{binary–digits: } \text{binary–digit } \]
\[ \text{binary–digit binary–digits } \]
\[ \text{binary–digit: one of } 0 1 \]

Integer literals in the range 0 to \( \text{max(int)} \) have type \text{int} and the remaining literals have type \text{uint}.

Rationale. Why are there no suffixes on integral literals? Suffixes, like those in C, are not necessary. Explicit conversions can then be used to change the type of the literal to another integer size.
Real literals are designated by the following syntax:

- **real-literal:**
  - `digits_opt . digits exponent-part_opt`
  - `digits . opt exponent-part`
  - `0x hexadecimal-digits_opt . digits p-exponent-part_opt`
  - `0X hexadecimal-digits_opt . digits p-exponent-part_opt`
  - `0x hexadecimal-digits-opt p-exponent-part`
  - `0X hexadecimal-digits_opt p-exponent-part`

- **exponent-part:**
  - `e sign_opt digits`
  - `E sign_opt digits`
- **p-exponent-part:**
  - `p sign_opt digits`
  - `P sign_opt digits`

**sign:** one of

- `+`
- `-`

**Rationale.** Why can’t a real literal end with ‘.’? There is a lexical ambiguity between real literals ending in ‘.’ and the range operator ‘..’ that makes it difficult to parse. For example, we want to parse `1..10` as a range from 1 to 10 without concern that `1.` is a real literal.

Hexadecimal real literals are supported with a hexadecimal integer and fractional part. Because ‘e’ could be a hexadecimal character, the exponent for these literals is instead marked with ‘p’ or ‘P’. The exponent value follows and is written in decimal.

The type of a real literal is `real`. Explicit conversions are necessary to change the size of the literal.

Imaginary literals are designated by the following syntax:

- **imaginary-literal:**
  - `real-literal i`
  - `integer-literal i`

The type of an imaginary literal is `imag`. Explicit conversions are necessary to change the size of the literal.

There are no complex literals. Rather, a complex value can be specified by adding or subtracting a real literal with an imaginary literal. Alternatively, a 2-tuple of integral or real expressions can be cast to a complex such that the first component becomes the real part and the second component becomes the imaginary part.

**Example.** The following expressions are identical: `1.0 + 2.0i` and `(1.0, 2.0):complex`.

String literals are designated by the following syntax:
Lexical Structure

string literal:
   " double-quote-delimited-characters_opt "
   ' single-quote-delimited-characters_opt '

double-quote-delimited-characters:
   string-character double-quote-delimited-characters_opt
   ' double-quote-delimited-characters_opt '

single-quote-delimited-characters:
   string-character single-quote-delimited-characters_opt
   " single-quote-delimited-characters_opt "

string-character:
   any character except the double quote, single quote, or new line
   simple-escape-character
   hexadecimal-escape-character

simple-escape-character: one of
   \ " ? \a \b \f \n \r \t \v

hexadecimal-escape-character:
   \x hexadecimal-digits

6.4.4 Operators and Punctuation

The following operators and punctuation are defined in the syntax of the language:

<table>
<thead>
<tr>
<th>symbols</th>
<th>use</th>
</tr>
</thead>
<tbody>
<tr>
<td>=</td>
<td>assignment</td>
</tr>
<tr>
<td>+= -= <em>= /= %</em> %= &amp;=</td>
<td>= ^= &amp;==</td>
</tr>
<tr>
<td>&lt;= &gt;&gt;&lt;&gt;</td>
<td>swap</td>
</tr>
<tr>
<td>. . by #</td>
<td>range specifier</td>
</tr>
<tr>
<td>. . &amp;</td>
<td></td>
</tr>
<tr>
<td>== != &lt;= &gt;= &lt; &gt;</td>
<td>range count operator</td>
</tr>
<tr>
<td>+ - * / % **</td>
<td>variable argument lists</td>
</tr>
<tr>
<td>:</td>
<td>logical/bitwise operators</td>
</tr>
<tr>
<td>;</td>
<td>relational operators</td>
</tr>
<tr>
<td>, . ? w ,</td>
<td>arithmetic operators</td>
</tr>
<tr>
<td></td>
<td>type specifier</td>
</tr>
<tr>
<td></td>
<td>statement separator</td>
</tr>
<tr>
<td></td>
<td>expression separator</td>
</tr>
<tr>
<td></td>
<td>member access</td>
</tr>
<tr>
<td></td>
<td>type query</td>
</tr>
<tr>
<td></td>
<td>string delimiters</td>
</tr>
</tbody>
</table>

6.4.5 Grouping Tokens

The following braces are part of the Chapel language:
<table>
<thead>
<tr>
<th>braces</th>
<th>use</th>
</tr>
</thead>
<tbody>
<tr>
<td>{ }</td>
<td>parenthesization, function calls, and tuples</td>
</tr>
<tr>
<td>[ ]</td>
<td>array literals, array types, forall expressions, and function calls</td>
</tr>
<tr>
<td>( )</td>
<td>domain literals, block statements</td>
</tr>
</tbody>
</table>
7 Types

Chapel is a statically typed language with a rich set of types. These include a set of predefined primitive types, enumerated types, structured types (classes, records, unions, tuples), data parallel types (ranges, domains, arrays), and synchronization types (sync, single, atomic).

The syntax of a type is as follows:

```
type-specifier:
  primitive-type
  enum-type
  structured-type
  dataparallel-type
  synchronization-type
```

Programmers can define their own enumerated types, classes, records, unions, and type aliases using type declaration statements:

```
type-declaration-statement:
  enum-declaration-statement
  class-declaration-statement
  record-declaration-statement
  union-declaration-statement
  type-alias-declaration-statement
```

These statements are defined in Sections §7.2, §15.1, §16.1, §17.2, and §7.6 respectively.

7.1 Primitive Types

The primitive types are: void, bool, int, uint, real, imag, complex, and string. They are defined in this section.

The primitive types are summarized by the following syntax:

```
primitive-type:
  void
  bool
  int
  uint
  real
  imag
  complex
  string

  ( integer-parameter-expression )

integer-parameter-expression:
  expression
```
If present, the parenthesized `integer-parameter-expression` must evaluate to a compile-time constant of integer type. See §8.4.1

*Open issue.* There is an expectation of future support for larger bit width primitive types depending on a platform’s native support for those types.

### 7.1.1 The Void Type

The `void` type is used to represent the lack of a value, for example when a function has no arguments and/or no return type.

There may be storage associated with a value of type `void`, in which case its lifetime obeys the same rules as a value of type `int`.

### 7.1.2 The Bool Type

Chapel defines a logical data type designated by the symbol `bool` with the two predefined values `true` and `false`. This default boolean type is stored using an implementation-defined number of bits. A particular number of bits can be specified using a parameter value following the `bool` keyword, such as `bool(8)` to request an 8-bit boolean value. Legal sizes are 8, 16, 32, and 64 bits.

Some statements require expressions of `bool` type and Chapel supports a special conversion of values to `bool` type when used in this context (§9.1.3).

### 7.1.3 Signed and Unsigned Integral Types

The integral types can be parameterized by the number of bits used to represent them. Valid bit-sizes are 8, 16, 32, and 64. The default signed integral type, `int`, and the default unsigned integral type, `uint` correspond to `int(64)` and `uint(64)` respectively.

The integral types and their ranges are given in the following table:

<table>
<thead>
<tr>
<th>Type</th>
<th>Minimum Value</th>
<th>Maximum Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>int(8)</td>
<td>-128</td>
<td>127</td>
</tr>
<tr>
<td>uint(8)</td>
<td>0</td>
<td>255</td>
</tr>
<tr>
<td>int(16)</td>
<td>-32768</td>
<td>32767</td>
</tr>
<tr>
<td>uint(16)</td>
<td>0</td>
<td>65535</td>
</tr>
<tr>
<td>int(32)</td>
<td>-2147483648</td>
<td>2147483647</td>
</tr>
<tr>
<td>uint(32)</td>
<td>0</td>
<td>4294967295</td>
</tr>
<tr>
<td>int(64).int</td>
<td>-9223372036854775808</td>
<td>9223372036854775807</td>
</tr>
<tr>
<td>uint(64).uint</td>
<td>0</td>
<td>18446744073709551615</td>
</tr>
</tbody>
</table>

The unary and binary operators that are pre-defined over the integral types operate with 32- and 64-bit precision. Using these operators on integral types represented with fewer bits results in an implicit conversion to the corresponding 32-bit types according to the rules defined in §9.1.
7.1.4 Real Types

Like the integral types, the real types can be parameterized by the number of bits used to represent them. The default real type, real, is 64 bits. The real types that are supported are machine-dependent, but usually include real(32) (single precision) and real(64) (double precision) following the IEEE 754 standard.

7.1.5 Imaginary Types

The imaginary types can be parameterized by the number of bits used to represent them. The default imaginary type, imag, is 64 bits. The imaginary types that are supported are machine-dependent, but usually include imag(32) and imag(64).

Rationale. The imaginary type is included to avoid numeric instabilities and under-optimized code stemming from always converting real values to complex values with a zero imaginary part.

7.1.6 Complex Types

Like the integral and real types, the complex types can be parameterized by the number of bits used to represent them. A complex number is composed of two real numbers so the number of bits used to represent a complex is twice the number of bits used to represent the real numbers. The default complex type, complex, is 128 bits; it consists of two 64-bit real numbers. The complex types that are supported are machine-dependent, but usually include complex(64) and complex(128).

The real and imaginary components can be accessed via the methods re and im. The type of these components is real. The standard Math module provides some functions on complex types. See [http://chapel.cray.com/docs/latest/modules/standard/Math.html](http://chapel.cray.com/docs/latest/modules/standard/Math.html)

Example. Given a complex number \( c \) with the value 3.14+2.72i, the expressions \( c.re \) and \( c.im \) refer to 3.14 and 2.72 respectively.

7.1.7 The String Type

Strings are a primitive type designated by the symbol string comprised of ASCII characters. Their length is unbounded.

Open issue. There is an expectation of future support for fixed-length strings.

Open issue. There is an expectation of future support for different character sets, possibly including internationalization.
7.2 Enumerated Types

Enumerated types are declared with the following syntax:

\[
\text{enum-declaration-statement:} \\
\text{enum identifier \{ enum-constant-list \}}
\]

\[
\text{enum-constant-list:} \\
\text{enum-constant} \\
\text{enum-constant, enum-constant-list_{opt}}
\]

\[
\text{enum-constant:} \\
\text{identifier init-part_{opt}}
\]

\[
\text{init-part:} \\
= \text{expression}
\]

The enumerated type can then be referenced by its name, as summarized by the following syntax:

\[
\text{enum-type:} \\
\text{identifier}
\]

An enumerated type defines a set of named constants that can be referred to via a member access on the enumerated type. These constants are treated as parameters of integral type. Each enumerated type is a distinct type. If the \text{init-part} is omitted, the \text{enum-constant} has an integral value one higher than the previous \text{enum-constant} in the enum, with the first having the value \text{1}.

**Example (enum.chpl).** The code

```plaintext
enum statesman { Aristotle, Roosevelt, Churchill, Kissinger }
```

defines an enumerated type with four constants. The function

```plaintext
proc quote(s: statesman) {
    select s {
        when statesman.Aristotle do
            writeln("All paid jobs absorb and degrade the mind.");
        when statesman.Roosevelt do
            writeln("Every reform movement has a lunatic fringe.");
        when statesman.Churchill do
            writeln("A joke is a very serious thing.");
        when statesman.Kissinger do
            { write("No one will ever win the battle of the sexes; ");
              writeln("there's too much fraternizing with the enemy."); } 
    }
}
```

outputs a quote from the given statesman. Note that enumerated constants must be prefixed by the enumerated type and a dot.
7.3 Structured Types

The structured types are summarized by the following syntax:

\[
\text{structured-type}:
\quad \text{class-type} \\
\quad \text{record-type} \\
\quad \text{union-type} \\
\quad \text{tuple-type}
\]

Classes are discussed in §15. Records are discussed in §16. Unions are discussed in §17. Tuples are discussed in §14.

7.3.1 Class Types

The class type defines a type that contains variables and constants, called fields, and functions, called methods. Classes are defined in §15. The class type can also contain type aliases and parameters. Such a class is generic and is defined in §22.3.

7.3.2 Record Types

The record type is similar to a class type; the primary difference is that a record is a value rather than a reference. Records are defined in §16.

7.3.3 Union Types

The union type defines a type that contains one of a set of variables. Like classes and records, unions may also define methods. Unions are defined in §17.

7.3.4 Tuple Types

A tuple is a light-weight record that consists of one or more anonymous fields. If all the fields are of the same type, the tuple is homogeneous. Tuples are defined in §14.
7.4 Data Parallel Types

The data parallel types are summarized by the following syntax:

```
dataparallel-type:
  range-type
  domain-type
  mapped-domain-type
  array-type
  index-type
```

Ranges and their index types are discussed in §18. Domains and their index types are discussed in §19. Arrays are discussed in §20.

7.4.1 Range Types

A range defines an integral sequence of some integral type. Ranges are defined in §18.

7.4.2 Domain, Array, and Index Types

A domain defines a set of indices. An array defines a set of elements that correspond to the indices in its domain. A domain’s indices can be of any type. Domains, arrays, and their index types are defined in §19 and §20.

7.5 Synchronization Types

The synchronization types are summarized by the following syntax:

```
synchronization-type:
  sync-type
  single-type
  atomic-type
```

Sync and single types are discussed in §24.3. The atomic type is discussed in §24.4.
7.6 Type Aliases

Type aliases are declared with the following syntax:

```plaintext

type-alias-declaration-statement:
  privacy-specifier*, config*, type type-alias-declaration-list ;
  external-type-alias-declaration-statement

type-alias-declaration-list:
  type-alias-declaration
  type-alias-declaration , type-alias-declaration-list

type-alias-declaration:
  identifier = type-specifier
  identifier
```

A type alias is a symbol that aliases the type specified in the `type-part`. A use of a type alias has the same meaning as using the type specified by `type-part` directly.

Type aliases defined at the module level are public by default. The optional `privacy-specifier` keywords are provided to specify or change this behavior. For more details on the visibility of symbols, see §12.4.2.

If the keyword `config` precedes the keyword `type`, the type alias is called a configuration type alias. Configuration type aliases can be set at compilation time via compilation flags or other implementation-defined means. The `type-specifier` in the program is ignored if the type-alias is alternatively set.

If the keyword `extern` precedes the `type` keyword, the type alias is external. The declared type name is used by Chapel for type resolution, but no type alias is generated by the backend. See the chapter on interoperability (§30) for more information on external types.

The `type-part` is optional in the definition of a class or record. Such a type alias is called an unspecified type alias. Classes and records that contain type aliases, specified or unspecified, are generic (§22.3.1).

Open issue. There is on going discussion on whether a type alias is a new type or simply an alias. The former should enable redefinition of default values, identity elements, etc.
8 Variables

A variable is a symbol that represents memory. Chapel is a statically-typed, type-safe language so every variable has a type that is known at compile-time and the compiler enforces that values assigned to the variable can be stored in that variable as specified by its type.

8.1 Variable Declarations

Variables are declared with the following syntax:

```
variable-declaration-statement:
variable-declaration:
  privacy-specifier_opt config-or-extern_opt variable-kind variable-declaration-list ;

config-or-extern: one of
  config extern

variable-kind: one of
  param const var

variable-declaration-list:
  variable-declaration
  variable-declaration , variable-declaration-list

variable-declaration:
  identifier-list type-part_opt initialization-part
  identifier-list type-part no-initialization-part_opt
  array-alias-declaration

type-part:
  : type-specifier

initialization-part:
  = expression

no-initialization-part:
  = noinit

identifier-list:
  identifier
  identifier , identifier-list
  tuple-grouped-identifier-list
  tuple-grouped-identifier-list , identifier-list

tuple-grouped-identifier-list:
( identifier-list )
```

A *variable-declaration-statement* is used to define one or more variables. If the statement is a top-level module statement, the variables are module level; otherwise they are local. Module level variables are discussed in §8.2. Local variables are discussed in §8.3.
The optional privacy-specifier keywords indicate the visibility of module level variables to outside modules. By default, variables are publicly visible. More details on visibility can be found in §12.4.2.

The optional keyword config specifies that the variables are configuration variables, described in Section §8.5. The optional keyword extern indicates that the variable is externally defined. Its name and type are used within the Chapel program for resolution, but no space is allocated for it and no initialization code emitted.

The variable-kind specifies whether the variables are parameters (param), constants (const), or regular variables (var). Parameters are compile-time constants whereas constants are runtime constants. Both levels of constants are discussed in §8.4.

The type-part of a variable declaration specifies the type of the variable. It is optional if the initialization-part is specified. If the type-part is omitted, the type of the variable is inferred using local type inference described in §8.1.3.

The initialization-part of a variable declaration specifies an initial expression to assign to the variable. If the initialization-part is omitted, the type-part must be present, and the variable is initialized to the default value of its type as described in §8.1.1.

If the no-initialization-part is present, the variable declaration does not initialize the variable to any value, as described in §8.1.2. The result of any read of an uninitialized variable is undefined until that variable is written.

Multiple variables can be defined in the same variable-declaration-list. The semantics of declaring multiple variables that share an initialization-part and/or type-part is defined in §8.1.4.

Multiple variables can be grouped together using a tuple notation as described in §14.6.2.

The array-alias-declaration is defined in §20.9.

### 8.1.1 Default Initialization

If a variable declaration has no initialization expression, a variable is initialized to the default value of its type. The default values are as follows:

<table>
<thead>
<tr>
<th>Type</th>
<th>Default Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>bool(*)</td>
<td>false</td>
</tr>
<tr>
<td>int(*)</td>
<td>0</td>
</tr>
<tr>
<td>uint(*)</td>
<td>0</td>
</tr>
<tr>
<td>real(*)</td>
<td>0.0</td>
</tr>
<tr>
<td>imag(*)</td>
<td>0.0i</td>
</tr>
<tr>
<td>complex(*)</td>
<td>0.0 + 0.0i</td>
</tr>
<tr>
<td>string</td>
<td>&quot;&quot;</td>
</tr>
<tr>
<td>enums</td>
<td>first enum constant</td>
</tr>
<tr>
<td>classes</td>
<td>nil</td>
</tr>
<tr>
<td>records</td>
<td>default constructed record</td>
</tr>
<tr>
<td>ranges</td>
<td>1..0 (empty sequence)</td>
</tr>
<tr>
<td>arrays</td>
<td>elements are default values</td>
</tr>
<tr>
<td>tuples</td>
<td>components are default values</td>
</tr>
<tr>
<td>sync/single</td>
<td>base default value and empty status</td>
</tr>
<tr>
<td>atomic</td>
<td>base default value</td>
</tr>
</tbody>
</table>
Open issue. In the case that the first enumerator in an enumeration type is offset from zero, as in

```
enum foo { red = 0xff0000, green = 0xff00, blue = 0xff }
```

the compiler has to look up the first named type to see what to use as the default.

An alternative would be to specify that the default value is the enumerator whose underlying value is zero.
But that approach also has issues, since the default value does not conform to any named enumerator.

### 8.1.2 Deferred Initialization

For performance purposes, a variable’s declaration can specify that the variable should not be default initialized by using the `noinit` keyword in place of an initialization expression. Since this variable should be written at a later point in order to be read properly, it must be a regular variable (`var`). It is incompatible with declarations that require the variable to remain unchanged throughout the program’s lifetime, such as `const` or `param`. Additionally, its type must be specified at declaration time.

The result of any read of this variable before it is written is undefined; it exists and therefore can be accessed, but no guarantees are made as to its contents.

### 8.1.3 Local Type Inference

If the type is omitted from a variable declaration, the type of the variable is defined to be the type of the initialization expression. With the exception of sync and single expressions, the declaration

```
var v = e;
```

is equivalent to

```
var v: e.type;
v = e;
```

for an arbitrary expression `e`. For expressions of sync or single type, this translation does not hold because the evaluation of `e` results in a default read of this expression. The type of the variable is thus equal to the base type of the sync or single expression.

### 8.1.4 Multiple Variable Declarations

All variables defined in the same `identifier-list` are defined such that they have the same type and value, and so that the type and initialization expression are evaluated only once.

```
proc g() { writeln("side effect"); return "a string"; }
var a, b = 1.0, c, d:int, e, f = g();
```

variables `a` and `b` are of type `real` with value `1.0`. Variables `c` and `d` are of type `int` and are initialized to the default value of `0`. Variables `e` and `f` are of type `string` with value "a string". The string "side effect" has been written to the display once. It is not evaluated twice.
The exact way that multiple variables are declared is defined as follows:

- If the variables in the `identifier-list` are declared with a type, but without an initialization expression as in
  ```
  var v1, v2, v3: t;
  ```
  for an arbitrary type expression `t`, then the declarations are rewritten so that the first variable is declared to be of type `t` and each later variable is declared to be of the type of the first variable as in
  ```
  var v1: t; var v2: v1.type; var v3: v1.type;
  ```

- If the variables in the `identifier-list` are declared without a type, but with an initialization expression as in
  ```
  var v1, v2, v3 = e;
  ```
  for an arbitrary expression `e`, then the declarations are rewritten so that the first variable is initialized by expression `e` and each later variable is initialized by the first variable as in
  ```
  var v1 = e; var v2 = v1; var v3 = v1;
  ```

- If the variables in the `identifier-list` are declared with both a type and an initialization expression as in
  ```
  var v1, v2, v3: t = e;
  ```
  for an arbitrary type expression `t` and an arbitrary expression `e`, then the declarations are rewritten so that the first variable is declared to be of type `t` and initialized by expression `e`, and each later variable is declared to be of the type of the first variable and initialized by the result of calling the function `readXX` on the first variable as in
  ```
  var v1: t = e; var v2: v1.type = readXX(v1); var v3: v1.type = readXX(v1);
  ```
  where the function `readXX` is defined as follows:
  ```
  proc readXX(x: sync) return x.readXX();
  proc readXX(x: single) return x.readXX();
  proc readXX(x) return x;
  ```

Note that the use of the helper function `readXX()` in this code fragment is solely for the purposes of illustration. It is not actually a part of Chapel’s semantics or implementation.

**Rationale.** This algorithm is complicated by the existence of `sync` and `single` variables. If these did not exist, we could rewrite any multi-variable declaration such that later variables were simply initialized by the first variable and the first variable was defined as if it appeared alone in the `identifier-list`. However, both `sync` and `single` variables require careful handling to avoid unintentional changes to their full/empty state.

### 8.2 Module Level Variables

Variables declared in statements that are in a module but not in a function or block within that module are module level variables. Module level variables can be accessed anywhere within that module after the declaration of that variable. If they are public, they can also be accessed in other modules that use that module.
8.3 Local Variables

Local variables are declared within block statements. They can only be accessed within the scope of that block statement (including all inner nested block statements and functions).

A local variable only exists during the execution of code that lies within that block statement. This time is called the lifetime of the variable. When execution has finished within that block statement, the local variable and the storage it represents is removed. Variables of class type are the sole exception. Constructors of class types create storage that is not associated with any scope. Such storage can be reclaimed as described in §15.9.

8.4 Constants

Constants are divided into two categories: parameters, specified with the keyword `param`, are compile-time constants and constants, specified with the keyword `const`, are runtime constants.

8.4.1 Compile-Time Constants

A compile-time constant, or “parameter”, must have a single value that is known statically by the compiler. Parameters are restricted to primitive and enumerated types.

Parameters can be assigned expressions that are parameter expressions. Parameter expressions are restricted to the following constructs:

- Literals of primitive or enumerated type.
- Parenthesized parameter expressions.
- Casts of parameter expressions to primitive or enumerated types.
- Applications of the unary operators `+`, `−`, `!`, and `~` on operands that are bool or integral parameter expressions.
- Applications of the unary operators `+` and `−` on operands that are real, imaginary or complex parameter expressions.
- Applications of the binary operators `+`, `−`, `∗`, `/`, `⋆⋆`, `&`, `&`, `| |`, `&`, `⋆`, `<`, `>`, `==`, `!=`, `<`, `>`, `<`, `>`, and `>` on operands that are bool or integral parameter expressions.

- Applications of the binary operators `+`, `−`, `∗`, `/`, `⋆⋆`, `==`, `!=`, `<`, `>`, `<`, and `>` on operands that are real, imaginary or complex parameter expressions.
- Applications of the string concatenation operator `+`, string comparison operators `==`, `!=`, `<`, `>`, `>=`, `<`, and `>` and the string length and ascii functions on parameter string expressions.
- The conditional expression where the condition is a parameter and the then- and else-expressions are parameters.
- Call expressions of parameter functions. See §13.7.2.
8.4.2 Runtime Constants

Runtime constants, or simply “constants”, do not have the restrictions that are associated with parameters. Constants can be of any type. They require an initialization expression and contain the value of that expression throughout their lifetime.

A variable of a class type that is a constant is a constant reference. That is, the variable always points to the object that it was initialized to reference. However, the fields of that object are allowed to be modified.

8.5 Configuration Variables

If the keyword `config` precedes the keyword `var`, `const`, or `param`, the variable, constant, or parameter is called a configuration variable, configuration constant, or configuration parameter respectively. Such variables, constants, and parameters must be at the module level.

The initialization of these variables can be set via implementation dependent means, such as command-line switches or environment variables. The initialization expression in the program is ignored if the initialization is alternatively set.

Configuration parameters are set at compilation time via compilation flags or other implementation-defined means. The value passed via these means can be an arbitrary Chapel expression as long as the expression can be evaluated at compile-time. If present, the value thus supplied overrides the default value appearing in the Chapel code.

Example (config-param.chpl). For example,

```chapel
config param rank = 2;
```

sets a integer parameter `rank` to 2. At compile-time, `rank` can be set via a configuration file or compile-line override to 3 or `2*n` or indeed to any other expression that can be evaluated at compile-time. The value supplied at compile time overrides the value 2 appearing in the code. In this example, the `rank` configuration variable can be used to write rank-independent code.

---

1It is assumed here that `n` is also a param variable.
9 Conversions

A conversion converts an expression of one type to another type, possibly changing its value. We refer to these two types the source and target types. Conversions can be either implicit (§9.1) or explicit (§9.2).

9.1 Implicit Conversions

An implicit conversion is a conversion that occurs implicitly, that is, not due to an explicit specification in the program. Implicit conversions occur at the locations in the program listed below. Each location determines the target type. The source and target types of an implicit conversion must be allowed. They determine whether and how the expression’s value changes.

An implicit conversion occurs at each of the following program locations:

- In an assignment, the expression on the right-hand side of the assignment is converted to the type of the variable or another lvalue on the left-hand side of the assignment.
- The actual argument of a function call or an operator is converted to the type of the corresponding formal argument, if the formal’s intent is `in` or `const in` or an abstract intent (§13.5.2) with the semantics of `in` or `const in`.
- The formal argument of a function call is converted to the type of the corresponding actual argument, if the formal’s intent is `out`.
- The return or yield expression within a function without a `ref` return intent is converted to the return type of that function.
- The condition of a conditional expression, conditional statement, while-do or do-while loop statement is converted to the boolean type (§9.1.3). A special rule defines the allowed source types and how the expression’s value changes in this case.

Implicit conversions are allowed between the following source and target types, as defined in the referenced subsections:

- numeric, boolean, and enumerated types (§9.1.1),
- class types (§15.8.2),
- record types (§16.9.3),
- integral types in the special case when the expression’s value is a compile-time constant (§9.1.2), and
- from an integral or class type to `bool` in certain cases (§9.1.3).

In addition, an implicit conversion from a type to the same type is allowed for any type. Such conversion does not change the value of the expression.

Implicit conversion is not transitive. That is, if an implicit conversion is allowed from type `T1` to `T2` and from `T2` to `T3`, that by itself does not allow an implicit conversion from `T1` to `T3`.

41
9.1.1 Implicit Numeric, Bool and Enumeration Conversions

Implicit conversions among numeric types are allowed when all values representable in the source type can also be represented in the target type, retaining their full precision. In addition, implicit conversions from types \texttt{int}(64) and \texttt{uint}(64) to types \texttt{real}(64) and \texttt{complex}(128) are allowed, even though they may result in a loss of precision.

\textit{Rationale.} We allow these additional conversions because they are an important convenience for application programmers. Therefore we are willing to lose precision in these cases. The largest real and complex types are chosen to retain precision as often as possible.

Any boolean type can be implicitly converted to any other boolean type, retaining the boolean value. Any boolean type can be implicitly converted to any integral type by representing \texttt{false} as 0 and \texttt{true} as 1, except (if applicable) a boolean cannot be converted to \texttt{int}(1).

\textit{Rationale.} We disallow implicit conversion of a boolean to a real, imaginary, or complex type because of the following. We expect that the cases where such a conversion is needed will more likely be unintended by the programmer. Marking those cases as errors will draw the programmer’s attention. If such a conversion is actually desired, a cast \[9.2\] can be inserted.

An expression of an enumerated type can be implicitly converted to an integral type, provided that all of the constants defined by the enumerated type are representable by the integral type.

Legal implicit conversions with numeric, boolean and enumerated types may thus be tabulated as follows:

<table>
<thead>
<tr>
<th>Source Type</th>
<th>bool(s)</th>
<th>uint(t)</th>
<th>int(t)</th>
<th>real(t)</th>
<th>imag(t)</th>
<th>complex(t)</th>
</tr>
</thead>
<tbody>
<tr>
<td>\texttt{bool}(s)</td>
<td>all (s, t)</td>
<td>all (s, t)</td>
<td>all (s; 2 \leq t)</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>\texttt{enum}</td>
<td>(see rules)</td>
<td>(see rules)</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>\texttt{uint}(s)</td>
<td>(s \leq t)</td>
<td>(s &lt; t)</td>
<td>(s \leq \text{mant}(t))</td>
<td></td>
<td>(s \leq \text{mant}(t/2))</td>
<td></td>
</tr>
<tr>
<td>\texttt{uint}(64)</td>
<td></td>
<td></td>
<td></td>
<td>\texttt{real}(64)</td>
<td></td>
<td>\texttt{complex}(128)</td>
</tr>
<tr>
<td>\texttt{int}(s)</td>
<td>(s \leq t)</td>
<td></td>
<td>(s \leq \text{mant}(t) + 1)</td>
<td></td>
<td>(s \leq \text{mant}(t/2) + 1)</td>
<td></td>
</tr>
<tr>
<td>\texttt{int}(64)</td>
<td></td>
<td></td>
<td></td>
<td>\texttt{real}(64)</td>
<td></td>
<td>\texttt{complex}(128)</td>
</tr>
<tr>
<td>\texttt{real}(s)</td>
<td></td>
<td></td>
<td></td>
<td>(s \leq t)</td>
<td></td>
<td>(s \leq t/2)</td>
</tr>
<tr>
<td>\texttt{imag}(s)</td>
<td></td>
<td></td>
<td></td>
<td>(s \leq t)</td>
<td>(s \leq t/2)</td>
<td></td>
</tr>
<tr>
<td>\texttt{complex}(s)</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td>(s \leq t)</td>
</tr>
</tbody>
</table>

Here, \texttt{mant}(i) is the number of bits in the (unsigned) mantissa of the \(i\)-bit floating-point type.\footnote{Conversions for the default integral and real types (\texttt{uint}, \texttt{complex}, etc.) are the same as for their explicitly-sized counterparts.}

\footnote{For the IEEE 754 format, \texttt{mant}(32) = 24 and \texttt{mant}(64) = 53.}
9.1.2 Implicit Compile-Time Constant Conversions

The following implicit conversion of a parameter is allowed:

- A parameter of type int(64) can be implicitly converted to int(8), int(16), int(32), or any unsigned integral type if the value of the parameter is within the range of the target type.

9.1.3 Implicit Statement Bool Conversions

In the condition of an if-statement, while-loop, and do-while-loop, the following implicit conversions to bool are supported:

- An expression of integral type is taken to be false if it is zero and is true otherwise.
- An expression of a class type is taken to be false if it is nil and is true otherwise.

9.2 Explicit Conversions

Explicit conversions require a cast in the code. Casts are defined in §10.9. Explicit conversions are supported between more types than implicit conversions, but explicit conversions are not supported between all types.

The explicit conversions are a superset of the implicit conversions. In addition to the following definitions, an explicit conversion from a type to the same type is allowed for any type. Such conversion does not change the value of the expression.

9.2.1 Explicit Numeric Conversions

Explicit conversions are allowed from any numeric type, boolean, or string to any other numeric type, boolean, or string.

When a bool is converted to a bool, int or uint of equal or larger size, its value is zero-extended to fit the new representation. When a bool is converted to a smaller bool, int or uint, its most significant bits are truncated (as appropriate) to fit the new representation.

When a int, uint, or real is converted to a bool, the result is false if the number was equal to 0 and true otherwise.

When an int is converted to a larger int or uint, its value is sign-extended to fit the new representation. When a uint is converted to a larger int or uint, its value is zero-extended. When an int or uint is converted to an int or uint of the same size, its binary representation is unchanged. When an int or uint is converted to a smaller int or uint, its value is truncated to fit the new representation.
**Future.** There are several kinds of integer conversion which can result in a loss of precision. Currently, the conversions are performed as specified, and no error is reported. In the future, we intend to improve type checking, so the user can be informed of potential precision loss at compile time, and actual precision loss at run time. Such cases include: When an int is converted to a uint and the original value is negative; When a uint is converted to an int and the sign bit of the result is true; When an int is converted to a smaller int or uint and any of the truncated bits differs from the original sign bit; When a uint is converted to a smaller int or uint and any of the truncated bits is true;

**Rationale.** For integer conversions, the default behavior of a program should be to produce a run-time error if there is a loss of precision. Thus, cast expressions not only give rise to a value conversion at run time, but amount to an assertion that the required precision is preserved. Explicit conversion procedures would be available in the run-time library so that one can perform explicit conversions that result in a loss of precision but do not generate a run-time diagnostic.

When converting from a real type to a larger real type, the represented value is preserved. When converting from a real type to a smaller real type, the closest representation in the target type is chosen.\(^2\)

When converting to a real type from an integer type, integer types smaller than int are first converted to int. Then, the closest representation of the converted value in the target type is chosen. The exact behavior of this conversion is implementation-defined.

When converting from real\((k)\) to complex\((2k)\), the original value is copied into the real part of the result, and the imaginary part of the result is set to zero. When converting from a real\((k)\) to a complex\((\ell)\) such that \(\ell > 2k\), the conversion is performed as if the original value is first converted to real\((\ell/2)\) and then to \(\ell\).

The rules for converting from imag to complex are the same as for converting from real, except that the imaginary part of the result is set using the input value, and the real part of the result is set to zero.

### 9.2.2 Explicit Tuple to Complex Conversion

A two-tuple of numerical values may be converted to a complex value. If the destination type is complex\((128)\), each member of the two-tuple must be convertible to real\((64)\). If the destination type is complex\((64)\), each member of the two-tuple must be convertible to real\((32)\). The first member of the tuple becomes the real part of the resulting complex value; the second member of the tuple becomes the imaginary part of the resulting complex value.

### 9.2.3 Explicit Enumeration Conversions

Explicit conversions are allowed from any enumerated type to any integer or real type, bool, or string, and vice versa.

When the target type is an integer type, the value is first converted to its underlying integer type and then to the target type, following the rules above for converting between integers.

When the target type is a real or complex type, the value is first converted to its underlying integer type and then to the target type.

\(^2\)When converting to a smaller real type, a loss of precision is expected. Therefore, there is no reason to produce a run-time diagnostic.
The conversion of an enumerated type to `imag` is not permitted.

When the target type is `bool`, the value is first converted to its underlying integer type. If the result is zero, the value of the `bool` is `false`; otherwise, it is `true`.

When the target type is `string`, the value becomes the name of the enumerator.

When the source type is `bool`, enumerators corresponding to the values 0 and 1 in the underlying integer type are selected, corresponding to input values of `false` and `true`, respectively.

When the source type is a real or integer type, the value is converted to the target type’s underlying integer type.

The conversion from `complex` and `imag` types to an enumerated type is not permitted.

When the source type is `string`, the enumerator whose name matches value of the input string is selected. If no such enumerator exists, a runtime error occurs.

### 9.2.4 Explicit Class Conversions

An expression of static class type `C` can be explicitly converted to a class type `D` provided that `C` is derived from `D` or `D` is derived from `C`.

When at run time the source expression refers to an instance of `D` or its subclass, its value is not changed. Otherwise, or when the source expression is `nil`, the result of the conversion is `nil`.

### 9.2.5 Explicit Record Conversions

An expression of record type `C` can be explicitly converted to another record type `D` provided that `C` is derived from `D`. There are no explicit record conversions that are not also implicit record conversions.
10 Expressions

Chapel provides the following expressions:

expression:
  literal-expression
  nil-expression
  variable-expression
  enum-constant-expression
  call-expression
  iterable-call-expression
  member-access-expression
  constructor-call-expression
  query-expression
  cast-expression
  lvalue-expression
  parenthesized-expression
  unary-expression
  binary-expression
  let-expression
  if-expression
  for-expression
  forall-expression
  reduce-expression
  scan-expression
  module-access-expression
  tuple-expression
  tuple-expand-expression
  locale-access-expression
  mapped-domain-expression

Individual expressions are defined in the remainder of this chapter and additionally as follows:

- forall, reduce, and scan §25
- module access §12.4.3
- tuple and tuple expand §14
- locale access §26.1.5
- mapped domain §27
- constructor calls §15.3
- nil §15.2.7
10.1 Literal Expressions

A literal value for any of the predefined types (§6.4.3) is a literal expression. Literal expressions are given by the following syntax:

\[
\text{literal-expression:} \\
\text{bool-literal} \\
\text{integer-literal} \\
\text{real-literal} \\
\text{imaginary-literal} \\
\text{string-literal} \\
\text{range-literal} \\
\text{domain-literal} \\
\text{array-literal}
\]

10.2 Variable Expressions

A use of a variable, constant, parameter, or formal argument, is itself an expression. The syntax of a variable expression is given by:

\[
\text{variable-expression:} \\
\text{identifier}
\]

10.3 Enumeration Constant Expression

A use of an enumeration constant is itself an expression. Such a constant must be preceded by the enumeration type name. The syntax of an enumeration constant expression is given by:

\[
\text{enum-constant-expression:} \\
\text{enum-type . identifier}
\]

For an example of using enumeration constants, see §7.2

10.4 Parenthesized Expressions

A parenthesized-expression is an expression that is delimited by parentheses as given by:

\[
\text{parenthesized-expression:} \\
(\text{expression})
\]

Such an expression evaluates to the expression. The parentheses are ignored and have only a syntactical effect.
10.5 Call Expressions

Functions and function calls are defined in §13.

10.6 Indexing Expressions

Indexing, for example into arrays, tuples, and domains, has the same syntax as a call expression.

Indexing is performed by an implicit invocation of the this method on the value being indexed, passing the indices as the actual arguments.

10.7 Member Access Expressions

Member access expressions provide access to a field or invoke a method of an instance of a class, record, or union. They are defined in §15.4 and §15.5, respectively.

member-access-expression:
  field-access-expression
  method-call-expression

10.8 The Query Expression

A query expression is used to query a type or value within a formal argument type expression. The syntax of a query expression is given by:

query-expression:
  ? identifier_opt

Querying is restricted to querying the type of a formal argument, the element type of a formal argument that is an array, the domain of a formal argument that is an array, the size of a primitive type, or a type or parameter field of a formal argument type.

The identifier can be omitted. This is useful for ensuring the genericity of a generic type that defines default values for all of its generic fields when specifying a formal argument as discussed in §22.1.5.

Example (query.chpl). The following code defines a generic function where the type of the first argument is queried and stored in the type alias $t$ and the domain of the second argument is queried and stored in the variable $D$:

```
proc foo(x: ?t, y: [?D] t) {
    for i in D do
        y[i] = x;
}
```
This allows a generic specification of assigning a particular value to all elements of an array. The value and the elements of the array are constrained to be the same type. This function can be rewritten without query expression as follows:

```plaintext
proc foo(x, y: [ ] x.type) {
for i in y.domain do
  y[i] = x;
}
```

There is an expectation that query expressions will be allowed in more places in the future.

### 10.9 Casts

A cast is specified with the following syntax:

```plaintext
cast-expression:
  expression : type-specifier
```

The expression is converted to the specified type. A cast expression invokes the corresponding explicit conversion ([§9.2](#)). A resolution error occurs if no such conversion exists.

### 10.10 LValue Expressions

An *lvalue* is an expression that can be used on the left-hand side of an assignment statement or on either side of a swap statement, that can be passed to a formal argument of a function that has `out`, `inout` or `ref` intent, or that can be returned by a function with a `ref` return intent ([§13.7.1](#)). Valid lvalue expressions include the following:

- Variable expressions.
- Member access expressions.
- Call expressions of functions with a `ref` return intent.
- Indexing expressions.

LValue expressions are given by the following syntax:

```plaintext
lvalue-expression:
  variable-expression
  member-access-expression
  call-expression
  parenthesized-expression
```

The syntax is less restrictive than the definition above. For example, not all *call-expressions* are lvalues.
10.11 Precedence and Associativity

The following table summarizes operator and expression precedence and associativity. Operators and expressions listed earlier have higher precedence than those listed later.

<table>

Expressions

Rationale. In general, our operator precedence is based on that of the C family of languages including C++, Java, Perl, and C#. We comment on a few of the differences and unique factors here.

We find that there is tension between the relative precedence of exponentiation, unary minus/plus, and casts. The following three expressions show our intuition for how these expressions should be parenthesized.

\[
\begin{align*}
-2^{\ast}4 & \quad \text{wants} \quad -(2^{\ast}4) \\
-2: \text{uint} & \quad \text{wants} \quad (-2): \text{uint} \\
2: \text{uint}^{\ast}4: \text{uint} & \quad \text{wants} \quad (2: \text{uint})^{\ast}(4: \text{uint})
\end{align*}
\]

Trying to support all three of these cases results in a circularity—exponentiation wants precedence over unary minus, unary minus wants precedence over casts, and casts want precedence over exponentiation. We chose to break the circularity by making unary minus have a lower precedence. This means that for the second case above:

\[
-2: \text{uint} \quad \text{requires} \quad (-2): \text{uint}
\]

We also chose to depart from the C family of languages by making unary plus/minus have lower precedence than binary multiplication, division, and modulus as in Fortran. We have found very few cases that distinguish between these cases. An interesting one is:

\[
\text{const minint} = \text{min}(\text{int}(32)) ; \\
\ldots \text{minint}/2 \ldots
\]

Intuitively, this should result in a positive value, yet C’s precedence rules results in a negative value due to asymmetry in modern integer representations. If we learn of cases that argue in favor of the C approach, we would likely reverse this decision in order to more closely match C.

We were tempted to diverge from the C precedence rules for the binary bitwise operators to make them bind less tightly than comparisons. This would allow us to interpret:

\[
a \mid b == 0 \quad \text{as} \quad (a \mid b) == 0
\]

However, given that no other popular modern language has made this change, we felt it unwise to stray from the pack. The typical rationale for the C ordering is to allow these operators to be used as non-short-circuiting logical operations.

In contrast to C, we give bitwise operations a higher precedence than binary addition/subtraction and comparison operators. This enables using the shift operators as shorthand for multiplication/division by powers of 2, and also makes it easier to extract and test a bitmapped field:

\[
(x \& \text{MASK}) == \text{MASK} \quad \text{as} \quad x \& \text{MASK} == \text{MASK} \\
a + b \ast \text{pow}(2, y) \quad \text{as} \quad a \ast b \ll y
\]

One final area of note is the precedence of reductions. Two common cases tend to argue for making reductions very low or very high in the precedence table:

\[
\begin{align*}
\text{max reduce } A - \text{min reduce } A & \quad \text{wants} \quad (\text{max reduce } A) - (\text{min reduce } A) \\
\text{max reduce } A \ast B & \quad \text{wants} \quad \text{max reduce } (A \ast B)
\end{align*}
\]

The first statement would require reductions to have a higher precedence than the arithmetic operators while the second would require them to be lower. We opted to make reductions have high precedence due to the argument that they tend to resemble unary operators. Thus, to support our intuition:
This choice also has the (arguably positive) effect of making the unparenthesized version of this statement result in an aggregate value if A and B are both aggregates—the reduction of A results in a scalar which promotes when being multiplied by B, resulting in an aggregate. Our intuition is that users who forget the parenthesis will learn of their error at compilation time because the resulting expression is not a scalar as expected.

### 10.12 Operator Expressions

The application of operators to expressions is itself an expression. The syntax of a unary expression is given by:

\[
\text{unary-expression:} \\
\quad \text{unary-operator expression}
\]

\[
\text{unary-operator: one of} \\
\quad + \ - \ \sim \ !
\]

The syntax of a binary expression is given by:

\[
\text{binary-expression:} \\
\quad \text{expression binary-operator expression}
\]

\[
\text{binary-operator: one of} \\
\quad + \ - \ * \ / \ % \ ** \ & \ | \ ^ \ <\ <\ >\ >\ \&\& \ || \ != \ <= \ >= \ <\ > \ by \ #
\]

The operators are defined in subsequent sections.

### 10.13 Arithmetic Operators

This section describes the predefined arithmetic operators. These operators can be redefined over different types using operator overloading ($\S$13.11).

For each operator, implicit conversions are applied to the operands of an operator such that they are compatible with one of the function forms listed, those listed earlier in the list being given preference. If no compatible implicit conversions exist, then a compile-time error occurs. In these cases, an explicit cast is required.

### 10.13.1 Unary Plus Operators

The unary plus operators are predefined as follows:
proc + (a: int(8)): int(8)
proc + (a: int(16)): int(16)
proc + (a: int(32)): int(32)
proc + (a: int(64)): int(64)

proc + (a: uint(8)): uint(8)
proc + (a: uint(16)): uint(16)
proc + (a: uint(32)): uint(32)
proc + (a: uint(64)): uint(64)

proc + (a: real(32)): real(32)
proc + (a: real(64)): real(64)

proc + (a: imag(32)): imag(32)
proc + (a: imag(64)): imag(64)

proc + (a: complex(64)): complex(64)
proc + (a: complex(128)): complex(128)

For each of these definitions, the result is the value of the operand.

10.13.2 Unary Minus Operators

The unary minus operators are predefined as follows:

proc - (a: int(8)): int(8)
proc - (a: int(16)): int(16)
proc - (a: int(32)): int(32)
proc - (a: int(64)): int(64)

proc - (a: real(32)): real(32)
proc - (a: real(64)): real(64)

proc - (a: imag(32)): imag(32)
proc - (a: imag(64)): imag(64)

proc - (a: complex(64)): complex(64)
proc - (a: complex(128)): complex(128)

For each of these definitions that return a value, the result is the negation of the value of the operand. For integral types, this corresponds to subtracting the value from zero. For real and imaginary types, this corresponds to inverting the sign. For complex types, this corresponds to inverting the signs of both the real and imaginary parts.

It is an error to try to negate a value of type uint(64). Note that negating a value of type uint(32) first converts the type to int(64) using an implicit conversion.

10.13.3 Addition Operators

The addition operators are predefined as follows:

proc + (a: int(8), b: int(8)): int(8)
proc + (a: int(16), b: int(16)): int(16)
proc + (a: int(32), b: int(32)): int(32)
proc + (a: int(64), b: int(64)): int(64)
Expressions

For each of these definitions that return a value, the result is the sum of the two operands.

It is a compile-time error to add a value of type `uint(64)` and a value of type `int(64)`.

Addition over a value of real type and a value of imaginary type produces a value of complex type. Addition of values of complex type and either real or imaginary types also produces a value of complex type.

10.13.4 Subtraction Operators

The subtraction operators are predefined as follows:

For each of these definitions that return a value, the result is the sum of the two operands.

It is a compile-time error to add a value of type `uint(64)` and a value of type `int(64)`.

Addition over a value of real type and a value of imaginary type produces a value of complex type. Addition of values of complex type and either real or imaginary types also produces a value of complex type.

10.13.4 Subtraction Operators

The subtraction operators are predefined as follows:

For each of these definitions that return a value, the result is the sum of the two operands.

It is a compile-time error to add a value of type `uint(64)` and a value of type `int(64)`.

Addition over a value of real type and a value of imaginary type produces a value of complex type. Addition of values of complex type and either real or imaginary types also produces a value of complex type.
For each of these definitions that return a value, the result is the value obtained by subtracting the second operand from the first operand.

It is a compile-time error to subtract a value of type `uint(64)` from a value of type `int(64)`, and vice versa.

Subtraction of a value of real type from a value of imaginary type, and vice versa, produces a value of complex type. Subtraction of values of complex type from either real or imaginary types, and vice versa, also produces a value of complex type.

### 10.13.5 Multiplication Operators

The multiplication operators are predefined as follows:

| proc | (a: `int`(8), b: `int`(8)): `int`(8) |
| proc | (a: `int`(16), b: `int`(16)): `int`(16) |
| proc | (a: `int`(32), b: `int`(32)): `int`(32) |
| proc | (a: `int`(64), b: `int`(64)): `int`(64) |
| proc | (a: `uint`(8), b: `uint`(8)): `uint`(8) |
| proc | (a: `uint`(16), b: `uint`(16)): `uint`(16) |
| proc | (a: `uint`(32), b: `uint`(32)): `uint`(32) |
| proc | (a: `uint`(64), b: `uint`(64)): `uint`(64) |
| proc | (a: `real`(32), b: `real`(32)): `real`(32) |
| proc | (a: `real`(64), b: `real`(64)): `real`(64) |
| proc | (a: `imag`(32), b: `imag`(32)): `real`(32) |
| proc | (a: `imag`(64), b: `imag`(64)): `real`(64) |
| proc | (a: `complex`(64), b: `complex`(64)): `complex`(64) |
| proc | (a: `complex`(128), b: `complex`(128)): `complex`(128) |
| proc | (a: `real`(32), b: `imag`(32)): `imag`(32) |
| proc | (a: `imag`(32), b: `real`(32)): `imag`(32) |
| proc | (a: `real`(64), b: `imag`(64)): `imag`(64) |
| proc | (a: `imag`(64), b: `real`(64)): `imag`(64) |
| proc | (a: `real`(32), b: `complex`(64)): `complex`(64) |
| proc | (a: `complex`(64), b: `real`(32)): `complex`(64) |
| proc | (a: `real`(64), b: `complex`(128)): `complex`(128) |
| proc | (a: `complex`(128), b: `real`(64)): `complex`(128) |
| proc | (a: `imag`(32), b: `complex`(64)): `complex`(64) |
| proc | (a: `complex`(64), b: `imag`(32)): `complex`(64) |
Expressions

```plaintext
proc *(a: imag(64), b: complex(128)): complex(128)
proc *(a: complex(128), b: imag(64)): complex(128)
```

For each of these definitions that return a value, the result is the product of the two operands.

It is a compile-time error to multiply a value of type \texttt{uint(64)} and a value of type \texttt{int(64)}.

Multiplication of values of imaginary type produces a value of real type. Multiplication over a value of real type and a value of imaginary type produces a value of imaginary type. Multiplication of values of complex type and either real or imaginary types produces a value of complex type.

10.13.6 Division Operators

The division operators are predefined as follows:

```plaintext
proc /(a: int(8), b: int(8)): int(8)
proc /(a: int(16), b: int(16)): int(16)
proc /(a: int(32), b: int(32)): int(32)
proc /(a: int(64), b: int(64)): int(64)
proc /(a: uint(8), b: uint(8)): uint(8)
proc /(a: uint(16), b: uint(16)): uint(16)
proc /(a: uint(32), b: uint(32)): uint(32)
proc /(a: uint(64), b: uint(64)): uint(64)
proc /(a: real(32), b: real(32)): real(32)
proc /(a: real(64), b: real(64)): real(64)
proc /(a: imag(32), b: imag(32)): real(32)
proc /(a: imag(64), b: imag(64)): real(64)
proc /(a: complex(64), b: complex(64)): complex(64)
proc /(a: complex(128), b: complex(128)): complex(128)
proc /(a: real(32), b: imag(32)): imag(32)
proc /(a: imag(32), b: real(32)): imag(32)
proc /(a: real(64), b: imag(64)): imag(64)
proc /(a: imag(64), b: real(64)): imag(64)
proc /(a: real(32), b: complex(64)): complex(64)
proc /(a: complex(64), b: real(32)): complex(64)
proc /(a: real(64), b: complex(128)): complex(128)
proc /(a: complex(128), b: real(64)): complex(128)
proc /(a: imag(32), b: complex(64)): complex(64)
proc /(a: complex(64), b: imag(32)): complex(64)
proc /(a: imag(64), b: complex(128)): complex(128)
proc /(a: complex(128), b: imag(64)): complex(128)
```

For each of these definitions that return a value, the result is the quotient of the two operands.

It is a compile-time error to divide a value of type \texttt{uint(64)} by a value of type \texttt{int(64)}, and vice versa.

Division of values of imaginary type produces a value of real type. Division over a value of real type and a value of imaginary type produces a value of imaginary type. Division of values of complex type and either real or imaginary types produces a value of complex type.
Expressions

When the operands are integers, the result (quotient) is also an integer. If $b$ does not divide $a$ exactly, then there are two candidate quotients $q_1$ and $q_2$ such that $b \times q_1$ and $b \times q_2$ are the two multiples of $b$ closest to $a$. The integer result $q$ is the candidate quotient which lies closest to zero.

### 10.13.7 Modulus Operators

The modulus operators are predefined as follows:

```
proc %(a: int(8), b: int(8)): int(8)
proc %(a: int(16), b: int(16)): int(16)
proc %(a: int(32), b: int(32)): int(32)
proc %(a: int(64), b: int(64)): int(64)

proc %(a: uint(8), b: uint(8)): uint(8)
proc %(a: uint(16), b: uint(16)): uint(16)
proc %(a: uint(32), b: uint(32)): uint(32)
proc %(a: uint(64), b: uint(64)): uint(64)
```

For each of these definitions that return a value, the result is the remainder when the first operand is divided by the second operand.

The sign of the result is the same as the sign of the dividend $a$, and the magnitude of the result is always smaller than that of the divisor $b$. For integer operands, the % and / operators are related by the following identity:

```plaintext
var q = a / b;
var r = a % b;
writeln(q * b + r == a);  // true
```

It is a compile-time error to take the remainder of a value of type `uint(64)` and a value of type `int(64)`, and vice versa.

There is an expectation that the predefined modulus operators will be extended to handle real, imaginary, and complex types in the future.

### 10.13.8 Exponentiation Operators

The exponentiation operators are predefined as follows:

```
proc **(a: int(8), b: int(8)): int(8)
proc **(a: int(16), b: int(16)): int(16)
proc **(a: int(32), b: int(32)): int(32)
proc **(a: int(64), b: int(64)): int(64)

proc **(a: uint(8), b: uint(8)): uint(8)
proc **(a: uint(16), b: uint(16)): uint(16)
proc **(a: uint(32), b: uint(32)): uint(32)
proc **(a: uint(64), b: uint(64)): uint(64)

proc **(a: real(32), b: real(32)): real(32)
proc **(a: real(64), b: real(64)): real(64)
```
Expressions

For each of these definitions that return a value, the result is the value of the first operand raised to the power of the second operand.

It is a compile-time error to take the exponent of a value of type $\text{uint}(64)$ by a value of type $\text{int}(64)$, and vice versa.

There is an expectation that the predefined exponentiation operators will be extended to handle imaginary and complex types in the future.

10.14 Bitwise Operators

This section describes the predefined bitwise operators. These operators can be redefined over different types using operator overloading (§13.11).

10.14.1 Bitwise Complement Operators

The bitwise complement operators are predefined as follows:

\[
\begin{align*}
\text{proc } \neg (a : \text{bool}) : \text{bool} \\
\text{proc } \neg (a : \text{int}(8)) : \text{int}(8) \\
\text{proc } \neg (a : \text{int}(16)) : \text{int}(16) \\
\text{proc } \neg (a : \text{int}(32)) : \text{int}(32) \\
\text{proc } \neg (a : \text{int}(64)) : \text{int}(64) \\
\text{proc } \neg (a : \text{uint}(8)) : \text{uint}(8) \\
\text{proc } \neg (a : \text{uint}(16)) : \text{uint}(16) \\
\text{proc } \neg (a : \text{uint}(32)) : \text{uint}(32) \\
\text{proc } \neg (a : \text{uint}(64)) : \text{uint}(64)
\end{align*}
\]

For each of these definitions, the result is the bitwise complement of the operand.

10.14.2 Bitwise And Operators

The bitwise and operators are predefined as follows:

\[
\begin{align*}
\text{proc } \& (a : \text{bool}, b : \text{bool}) : \text{bool} \\
\text{proc } \& (a : \text{int}(w), b : \text{int}(w)) : \text{int}(w) \\
\text{proc } \& (a : \text{uint}(w), b : \text{uint}(w)) : \text{uint}(w) \\
\text{proc } \& (a : \text{int}(w), b : \text{uint}(w)) : \text{uint}(w) \\
\text{proc } \& (a : \text{uint}(w), b : \text{int}(w)) : \text{uint}(w)
\end{align*}
\]

For each of these definitions, the result is computed by applying the logical and operation to the bits of the operands.

Chapel allows mixing signed and unsigned integers of the same size when passing them as arguments to bitwise and. In the mixed case the result is of the same size as the arguments and is unsigned. No run-time error is issued, even if the apparent sign changes as the required conversions are performed.
Expressions

Rationale. The mathematical meaning of integer arguments is discarded when they are passed to bitwise operators. Instead the arguments are treated simply as bit vectors. The bit-vector meaning is preserved when converting between signed and unsigned of the same size. The choice of unsigned over signed as the result type in the mixed case reflects the semantics of standard C.

10.14.3 Bitwise Or Operators

The bitwise or operators are predefined as follows:

\[
\begin{align*}
\text{proc} & \mid (a: \text{bool}, b: \text{bool}): \text{bool} \\
\text{proc} & \mid (a: \text{int}(\text{w}), b: \text{int}(\text{w})): \text{int}(\text{w}) \\
\text{proc} & \mid (a: \text{uint}(\text{w}), b: \text{uint}(\text{w})): \text{uint}(\text{w}) \\
\text{proc} & \mid (a: \text{int}(\text{w}), b: \text{uint}(\text{w})): \text{uint}(\text{w}) \\
\text{proc} & \mid (a: \text{uint}(\text{w}), b: \text{int}(\text{w})): \text{uint}(\text{w})
\end{align*}
\]

For each of these definitions, the result is computed by applying the logical or operation to the bits of the operands. Chapel allows mixing signed and unsigned integers of the same size when passing them as arguments to bitwise or. No run-time error is issued, even if the apparent sign changes as the required conversions are performed.

Rationale. The same as for bitwise and (§10.14.2).

10.14.4 Bitwise Xor Operators

The bitwise xor operators are predefined as follows:

\[
\begin{align*}
\text{proc} & \mid (a: \text{bool}, b: \text{bool}): \text{bool} \\
\text{proc} & \mid (a: \text{int}(\text{w}), b: \text{int}(\text{w})): \text{int}(\text{w}) \\
\text{proc} & \mid (a: \text{uint}(\text{w}), b: \text{uint}(\text{w})): \text{uint}(\text{w}) \\
\text{proc} & \mid (a: \text{int}(\text{w}), b: \text{uint}(\text{w})): \text{uint}(\text{w}) \\
\text{proc} & \mid (a: \text{uint}(\text{w}), b: \text{int}(\text{w})): \text{uint}(\text{w})
\end{align*}
\]

For each of these definitions, the result is computed by applying the XOR operation to the bits of the operands. Chapel allows mixing signed and unsigned integers of the same size when passing them as arguments to bitwise xor. No run-time error is issued, even if the apparent sign changes as the required conversions are performed.

Rationale. The same as for bitwise and (§10.14.2).

10.15 Shift Operators

This section describes the predefined shift operators. These operators can be redefined over different types using operator overloading (§13.11).

The shift operators are predefined as follows:
The type of the second actual argument must be any integral type.

The **<<** operator shifts the bits of a left by the integer b. The new low-order bits are set to zero.

The **>>** operator shifts the bits of a right by the integer b. When a is negative, the new high-order bits are set to one; otherwise the new high-order bits are set to zero.

The value of b must be non-negative.

## 10.16 Logical Operators

This section describes the predefined logical operators. These operators can be redefined over different types using operator overloading (§13.11).

### 10.16.1 The Logical Negation Operator

The logical negation operator is predefined for booleans and integers as follows:

```go
proc !(a: bool): bool
proc !(a: int(?w)): bool
proc !(a: uint(?w)): bool
```

For the boolean form, the result is the logical negation of the operand. For the integer forms, the result is true if the operand is zero and false otherwise.
10.16.2 The Logical And Operator

The logical and operator is predefined over bool type. It returns true if both operands evaluate to true; otherwise it returns false. If the first operand evaluates to false, the second operand is not evaluated and the result is false.

The logical and operator over expressions $a$ and $b$ given by

\[ a \&\& b \]

is evaluated as the expression

\[ \text{if isTrue}(a) \text{ then isTrue}(b) \text{ else false} \]

The function isTrue is predefined over bool type as follows:

\[ \text{proc isTrue}(a:\text{bool}) \text{ return } a; \]

Overloading the logical and operator over other types is accomplished by overloading the isTrue function over other types.

10.16.3 The Logical Or Operator

The logical or operator is predefined over bool type. It returns true if either operand evaluate to true; otherwise it returns false. If the first operand evaluates to true, the second operand is not evaluated and the result is true.

The logical or operator over expressions $a$ and $b$ given by

\[ a \|\| b \]

is evaluated as the expression

\[ \text{if isTrue}(a) \text{ then true else isTrue}(b) \]

The function isTrue is predefined over bool type as described in §10.16.2. Overloading the logical or operator over other types is accomplished by overloading the isTrue function over other types.

10.17 Relational Operators

This section describes the predefined relational operators. These operators can be redefined over different types using operator overloading (§13.11).
10.17.1 Ordered Comparison Operators

The “less than” comparison operators are predefined over numeric types as follows:

\[
\begin{align*}
\text{proc} & <(a: \text{int}(8), b: \text{int}(8)): \text{bool} \\
\text{proc} & <(a: \text{int}(16), b: \text{int}(16)): \text{bool} \\
\text{proc} & <(a: \text{int}(32), b: \text{int}(32)): \text{bool} \\
\text{proc} & <(a: \text{int}(64), b: \text{int}(64)): \text{bool} \\
\text{proc} & <(a: \text{uint}(8), b: \text{uint}(8)): \text{bool} \\
\text{proc} & <(a: \text{uint}(16), b: \text{uint}(16)): \text{bool} \\
\text{proc} & <(a: \text{uint}(32), b: \text{uint}(32)): \text{bool} \\
\text{proc} & <(a: \text{uint}(64), b: \text{uint}(64)): \text{bool} \\
\text{proc} & <(a: \text{real}(32), b: \text{real}(32)): \text{bool} \\
\text{proc} & <(a: \text{real}(64), b: \text{real}(64)): \text{bool} \\
\text{proc} & <(a: \text{imag}(32), b: \text{imag}(32)): \text{bool} \\
\text{proc} & <(a: \text{imag}(64), b: \text{imag}(64)): \text{bool}
\end{align*}
\]

The result of \(a < b\) is true if \(a\) is less than \(b\); otherwise the result is false.

The “greater than” comparison operators are predefined over numeric types as follows:

\[
\begin{align*}
\text{proc} & >(a: \text{int}(8), b: \text{int}(8)): \text{bool} \\
\text{proc} & >(a: \text{int}(16), b: \text{int}(16)): \text{bool} \\
\text{proc} & >(a: \text{int}(32), b: \text{int}(32)): \text{bool} \\
\text{proc} & >(a: \text{int}(64), b: \text{int}(64)): \text{bool} \\
\text{proc} & >(a: \text{uint}(8), b: \text{uint}(8)): \text{bool} \\
\text{proc} & >(a: \text{uint}(16), b: \text{uint}(16)): \text{bool} \\
\text{proc} & >(a: \text{uint}(32), b: \text{uint}(32)): \text{bool} \\
\text{proc} & >(a: \text{uint}(64), b: \text{uint}(64)): \text{bool} \\
\text{proc} & >(a: \text{real}(32), b: \text{real}(32)): \text{bool} \\
\text{proc} & >(a: \text{real}(64), b: \text{real}(64)): \text{bool} \\
\text{proc} & >(a: \text{imag}(32), b: \text{imag}(32)): \text{bool} \\
\text{proc} & >(a: \text{imag}(64), b: \text{imag}(64)): \text{bool}
\end{align*}
\]

The result of \(a > b\) is true if \(a\) is greater than \(b\); otherwise the result is false.

The “less than or equal to” comparison operators are predefined over numeric types as follows:

\[
\begin{align*}
\text{proc} & <=(a: \text{int}(8), b: \text{int}(8)): \text{bool} \\
\text{proc} & <=(a: \text{int}(16), b: \text{int}(16)): \text{bool} \\
\text{proc} & <=(a: \text{int}(32), b: \text{int}(32)): \text{bool} \\
\text{proc} & <=(a: \text{int}(64), b: \text{int}(64)): \text{bool} \\
\text{proc} & <=(a: \text{uint}(8), b: \text{uint}(8)): \text{bool} \\
\text{proc} & <=(a: \text{uint}(16), b: \text{uint}(16)): \text{bool} \\
\text{proc} & <=(a: \text{uint}(32), b: \text{uint}(32)): \text{bool} \\
\text{proc} & <=(a: \text{uint}(64), b: \text{uint}(64)): \text{bool} \\
\text{proc} & <=(a: \text{real}(32), b: \text{real}(32)): \text{bool} \\
\text{proc} & <=(a: \text{real}(64), b: \text{real}(64)): \text{bool} \\
\text{proc} & <=(a: \text{imag}(32), b: \text{imag}(32)): \text{bool} \\
\text{proc} & <=(a: \text{imag}(64), b: \text{imag}(64)): \text{bool}
\end{align*}
\]
The result of \( a \leq b \) is true if \( a \) is less than or equal to \( b \); otherwise the result is false.

The “greater than or equal to” comparison operators are predefined over numeric types as follows:

```plaintext
proc \( \geq \) (a: int(8), b: int(8)): bool
proc \( \geq \) (a: int(16), b: int(16)): bool
proc \( \geq \) (a: int(32), b: int(32)): bool
proc \( \geq \) (a: int(64), b: int(64)): bool
proc \( \geq \) (a: uint(8), b: uint(8)): bool
proc \( \geq \) (a: uint(16), b: uint(16)): bool
proc \( \geq \) (a: uint(32), b: uint(32)): bool
proc \( \geq \) (a: uint(64), b: uint(64)): bool
proc \( \geq \) (a: real(32), b: real(32)): bool
proc \( \geq \) (a: real(64), b: real(64)): bool
proc \( \geq \) (a: imag(32), b: imag(32)): bool
proc \( \geq \) (a: imag(64), b: imag(64)): bool
```

The result of \( a \geq b \) is true if \( a \) is greater than or equal to \( b \); otherwise the result is false.

The ordered comparison operators are predefined over strings as follows:

```plaintext
proc < (a: string, b: string): bool
proc > (a: string, b: string): bool
proc <= (a: string, b: string): bool
proc >= (a: string, b: string): bool
```

Comparisons between strings are defined based on the ordering of the character set used to represent the string, which is applied elementwise to the string’s characters in order.

### 10.17.2 Equality Comparison Operators

The equality comparison operators \( == \) and \( != \) are predefined over bool and the numeric types as follows:

```plaintext
proc \( == \) (a: int(8), b: int(8)): bool
proc \( == \) (a: int(16), b: int(16)): bool
proc \( == \) (a: int(32), b: int(32)): bool
proc \( == \) (a: int(64), b: int(64)): bool
proc \( == \) (a: uint(8), b: uint(8)): bool
proc \( == \) (a: uint(16), b: uint(16)): bool
proc \( == \) (a: uint(32), b: uint(32)): bool
proc \( == \) (a: uint(64), b: uint(64)): bool
proc \( == \) (a: real(32), b: real(32)): bool
proc \( == \) (a: real(64), b: real(64)): bool
proc \( == \) (a: imag(32), b: imag(32)): bool
proc \( == \) (a: imag(64), b: imag(64)): bool
proc \( == \) (a: complex(64), b: complex(64)): bool
proc \( == \) (a: complex(128), b: complex(128)): bool
proc \( != \) (a: int(8), b: int(8)): bool
proc \( != \) (a: int(16), b: int(16)): bool
proc \( != \) (a: int(32), b: int(32)): bool
proc \( != \) (a: int(64), b: int(64)): bool
```
Expressions

\begin{verbatim}
proc !=(a: uint(8), b: uint(8)): bool
proc !=(a: uint(16), b: uint(16)): bool
proc !=(a: uint(32), b: uint(32)): bool
proc !=(a: uint(64), b: uint(64)): bool

proc !=(a: real(32), b: real(32)): bool
proc !=(a: real(64), b: real(64)): bool

proc !=(a: imag(32), b: imag(32)): bool
proc !=(a: imag(64), b: imag(64)): bool

proc !=(a: complex(64), b: complex(64)): bool
proc !=(a: complex(128), b: complex(128)): bool
\end{verbatim}

The result of \( a == b \) is true if \( a \) and \( b \) contain the same value; otherwise the result is false. The result of \( a != b \) is equivalent to \( !(a == b) \).

The equality comparison operators are predefined over classes as follows:

\begin{verbatim}
proc ==(*a: object, b: object): bool
proc !=(a: object, b: object): bool
\end{verbatim}

The result of \( a == b \) is true if \( a \) and \( b \) reference the same storage location; otherwise the result is false. The result of \( a != b \) is equivalent to \( !(a == b) \).

Default equality comparison operators are generated for records if the user does not define them. These operators are described in [16.9.2].

The equality comparison operators are predefined over strings as follows:

\begin{verbatim}
proc ==(*a: string, b: string): bool
proc !=(a: string, b: string): bool
\end{verbatim}

The result of \( a == b \) is true if the sequence of characters in \( a \) matches exactly the sequence of characters in \( b \); otherwise the result is false. The result of \( a != b \) is equivalent to \( !(a == b) \).

10.18 Miscellaneous Operators

This section describes several miscellaneous operators. These operators can be redefined over different types using operator overloading ([13.11]).

10.18.1 The String Concatenation Operator

The string concatenation operator + is predefined over numeric, boolean, and enumerated types with strings. It casts its operands to string type and concatenates them together.

Example (string-concat.chpl). The code

```
"result: "+i
```

where \( i \) is an integer appends the string representation of \( i \) to the string literal "result: ". If \( i \) is 3, then the resulting string would be "result: 3".
10.18.2 The By Operator

The operator $\texttt{by}$ is predefined on ranges and rectangular domains. It is described in §18.5.1 for ranges and §19.8.2 for domains.

10.18.3 The Range Count Operator

The operator #$ is predefined on ranges. It is described in §18.5.3.

10.19 Let Expressions

A let expression allows variables to be declared at the expression level and used within that expression. The syntax of a let expression is given by:

\[
\texttt{let-expression}: \quad \texttt{let} \quad \texttt{variable-declaration-list} \quad \texttt{in} \quad \texttt{expression}
\]

The scope of the variables is the let-expression.

Example (let.chpl). Let expressions are useful for defining variables in the context of an expression. In the code

\[
\texttt{let} \quad x: \texttt{real} = a \times b, \quad y = x \times x \quad \texttt{in} \quad 1/y
\]

the value determined by $a \times b$ is computed and converted to type real if it is not already a real. The square of the real is then stored in $y$ and the result of the expression is the reciprocal of that value.

10.20 Conditional Expressions

A conditional expression is given by the following syntax:

\[
\texttt{if-expression}: \quad \texttt{if} \quad \texttt{expression} \quad \texttt{then} \quad \texttt{expression} \quad \texttt{else} \quad \texttt{expression}
\]

The conditional expression is evaluated in two steps. First, the expression following the \texttt{if} keyword is evaluated. Then, if the expression evaluated to true, the expression following the \texttt{then} keyword is evaluated and taken to be the value of this expression. Otherwise, the expression following the \texttt{else} keyword is evaluated and taken to be the value of this expression. In both cases, the unselected expression is not evaluated.

The \texttt{else} clause can be omitted only when the conditional expression is nested immediately inside a for or forall expression. Such an expression is used to filter predicates as described in §§10.21.1 and 25.2.4 respectively.

Example (condexp.chpl). This example shows how if-then-else can be used in a context in which an expression is expected. The code
writehalf(8);
writehalf(21);
writehalf(1000);

proc writehalf(i: int) {
    var half = if (i % 2) then i/2 + 1 else i/2;
    writeln("Half of ",i," is ",half);
}

produces the output
Half of 8 is 4
Half of 21 is 11
Half of 1000 is 500

10.21 For Expressions

A for expression is given by the following syntax:

\[
\text{for-expression:} \\
\text{for index-var-declaration in iterable-expression do expression} \\
\text{for iterable-expression do expression}
\]

The for expression executes a for loop (§11.9), evaluates the body expression on each iteration of the loop, and returns the resulting values as a collection. The size and shape of that collection are determined by the iterable-expression.

10.21.1 Filtering Predicates in For Expressions

A conditional expression that is immediately enclosed in a for expression and does not require an else clause filters the iterations of the for expression. The iterations for which the condition does not hold are not reflected in the result of the for expression.

Example (yieldPredicates.chpl). The code

\[
\text{var A = for i in 1..10 do if i % 3 != 0 then i;}
\]

declares an array A that is initialized to the integers between 1 and 10 that are not divisible by 3.
11 Statements

Chapel is an imperative language with statements that may have side effects. Statements allow for the sequencing of program execution. Chapel provides the following statements:

- `statement`
- `block statement`
- `expression statement`
- `assignment statement`
- `swap statement`
- `io statement`
- `conditional statement`
- `select statement`
- `while do statement`
- `do while statement`
- `for statement`
- `label statement`
- `break statement`
- `continue statement`
- `param for statement`
- `use statement`
- `empty statement`
- `return statement`
- `yield statement`
- `module declaration statement`
- `procedure declaration statement`
- `external procedure declaration statement`
- `exported procedure declaration statement`
- `iterator declaration statement`
- `method declaration statement`
- `type declaration statement`
- `variable declaration statement`
- `remote variable declaration statement`
- `on statement`
- `cobegin statement`
- `coforall statement`
- `begin statement`
- `sync statement`
- `serial statement`
- `atomic statement`
- `forall statement`
- `delete statement`

Individual statements are defined in the remainder of this chapter and additionally as follows:

- `return` §13.8
- `yield` §21.2
- `module declaration` §12
• procedure declaration §13.2
• external procedure declaration §30.1.1
• exporting procedure declaration §30.1.2
• iterator declaration §21.1
• method declaration §15.1.4
• type declaration §7
• variable declaration §8.1
• remote variable declaration §26.2.1
• on statement §26.2
• cobegin, coforall, begin, sync, serial and atomic statements §24
• forall §25
• delete §15.9

11.1 Blocks

A block is a statement or a possibly empty list of statements that form their own scope. A block is given by

\[
\text{block-statement:
}\begin{array}{c}
\{ \text{statements}_{\text{opt}} \} \\
\text{statements:
}\end{array}
\text{statement
}\text{statement statements}
\]

Variables defined within a block are local variables (§8.3).

The statements within a block are executed serially unless the block is in a cobegin statement (§24.5).

11.2 Expression Statements

The expression statement evaluates an expression solely for side effects. The syntax for an expression statement is given by

\[
\text{expression-statement:
}\begin{array}{c}
\text{variable-expression ;
}\text{member-access-expression ;
}\text{call-expression ;
}\text{constructor-call-expression ;
}\text{let-expression ;}
\end{array}
\]

11.3 Assignment Statements

An assignment statement assigns the value of an expression to another expression, for example, a variable. Assignment statements are given by

\[
\text{assignment-statement:} \\
\quad \text{lvalue-expression assignment-operator expression}
\]

\[
\text{assignment-operator: one of} \\
\quad = \quad += \quad -= \quad *= \quad %= \quad &= \quad |\|= \quad &\&= \quad ||= \quad <= \quad >=
\]

The assignment operators that contain a binary operator symbol as a prefix are \textit{compound assignment} operators. The remaining assignment operator = is called \textit{simple assignment}.

The expression on the left-hand side of the assignment operator must be a valid lvalue (§10.10). It is evaluated before the expression on the right-hand side of the assignment operator, which can be any expression.

When the left-hand side is of a numerical type, there is an implicit conversion (§9.1) of the right-hand side expression to the type of the left-hand side expression. Additionally, for simple assignment, if the left-hand side is of Boolean type, the right-hand side is implicitly converted to the type of the left-hand side (i.e. a \texttt{bool(?w)} with the same width \(w\)).

For simple assignment, the validity and semantics of assigning between classes (§15.8.1), records (§16.9.1), unions (§17.3), tuples (§14.5), ranges (§18.4.1), domains (§19.8.1), and arrays (§20.5) are discussed in these later sections.

A compound assignment is shorthand for applying the binary operator to the left- and right-hand side expressions and then assigning the result to the left-hand side expression. For numerical types, the left-hand side expression is evaluated only once, and there is an implicit conversion of the result of the binary operator to the type of the left-hand side expression. Thus, for example, \(x += y\) is equivalent to \(x = x + y\) where the expression \(x\) is evaluated once.

For all other compound assignments, Chapel provides a completely generic catch-all implementation defined in the obvious way. For example:

```chapel
inline proc +=(ref lhs, rhs) {
    lhs = lhs + rhs;
}
```

Thus, compound assignment can be used with operands of arbitrary types, provided that the following provisions are met: If the type of the left-hand argument of a compound assignment operator \(\text{op=}\) is \(L\) and that of the right-hand argument is \(R\), then a definition for the corresponding binary operator \(\text{op}\) exists, such that \(L\) is coercible to the type of its left-hand formal and \(R\) is coercible to the type of its right-hand formal. Further, the result of \(\text{op}\) must be coercible to \(L\), and there must exist a definition for simple assignment between objects of type \(L\).

Both simple and compound assignment operators can be overloaded for different types using operator overloading (§13.11). In such an overload, the left-hand side expression should have \texttt{ref} intent and be modified within the body of the function. The return type of the function should be \texttt{void}.
11.4 The Swap Statement

The swap statement indicates to swap the values in the expressions on either side of the swap operator. Since both expressions are assigned to, each must be a valid lvalue expression (§10.10).

The swap operator can be overloaded for different types using operator overloading (§13.11).

\[
\text{swap} - \text{statement:} \\
\text{lvalue-expression swap-operator lvalue-expression}
\]

\[
\text{swap} - \text{operator:} \\
\left\langle\Rightarrow\right\rangle
\]

To implement the swap operation, the compiler uses temporary variables as necessary.

**Example.** When resolved to the default swap operator, the following swap statement

```
var a, b: real;

a <=> b;
```

is semantically equivalent to:

```
const t = b;
b = a;
a = t;
```

11.5 The I/O Statement

The I/O operator indicates writing to the left-hand-side the value in the right-hand-side; or reading from the left-hand-side and storing the result in the variable on the right-hand-side. This operator can be chained with other I/O operator calls.

The I/O operator can be overloaded for different types using operator overloading (§13.11).

\[
\text{io} - \text{statement:} \\
\text{io-expression io-operator expression}
\]

\[
\text{io} - \text{expression:} \\
\text{expression} \text{io-expression io-operator expression}
\]

\[
\text{io} - \text{operator:} \\
\left\langle\sim\rightarrow\right\rangle
\]

See the module documentation on I/O for details on how to use the I/O statement.

**Example.** In the example below,

```
var w: Writer;
var a: real;
var b: int;

w <~> a <~> b;
```

the I/O operator is left-associative and indicates writing \(a\) and then \(b\) to \(w\) in this case.
11.6  The Conditional Statement

The conditional statement allows execution to choose between two statements based on the evaluation of an expression of bool type. The syntax for a conditional statement is given by

```plaintext
conditional-statement:
  if expression then statement else-part
  if expression block-statement else-part

else-part:
  else statement
```

A conditional statement evaluates an expression of bool type. If the expression evaluates to true, the first statement in the conditional statement is executed. If the expression evaluates to false and the optional else-clause exists, the statement following the else keyword is executed.

If the expression is a parameter, the conditional statement is folded by the compiler. If the expression evaluates to true, the first statement replaces the conditional statement. If the expression evaluates to false, the second statement, if it exists, replaces the conditional statement; if the second statement does not exist, the conditional statement is removed.

Each statement embedded in the `conditional-statement` has its own scope whether or not an explicit block surrounds it.

If the statement that immediately follows the optional `then` keyword is a conditional statement and it is not in a block, the else-clause is bound to the nearest preceding conditional statement without an else-clause. The statement in the else-clause can be a conditional statement, too.

**Example (conditionals.chpl).** The following function prints `two` when `x` is 2 and `B`, `four` when `x` is 4.

```plaintext
proc condtest(x:int) {
  if x > 3 then
    if x > 5 then
      write("A,");
    else
      write("B,");
  else
    write("B,");

  if x == 2 then
    writeln("two");
  else if x == 4 then
    writeln("four");
  else
    writeln("other");
}
```

11.7  The Select Statement

The select statement is a multi-way variant of the conditional statement. The syntax is given by:
Statements

select-statement:

\textbf{select} expression \{ when-statements \}

when-statements:

when-statement

when-statement when-statements

when-statement:

\textbf{when} expression-list \textbf{do} statement
\textbf{when} expression-list block-statement
\textbf{otherwise} statement

expression-list:

expression
expression, expression-list

The expression that follows the keyword \textbf{select}, the select expression, is evaluated once and its value is then compared with the list of case expressions following each \textbf{when} keyword. These values are compared using the equality operator \texttt{==}. If the expressions cannot be compared with the equality operator, a compile-time error is generated. The first case expression that contains an expression where that comparison is \texttt{true} will be selected and control transferred to the associated statement. If the comparison is always \texttt{false}, the statement associated with the keyword \texttt{otherwise}, if it exists, will be selected and control transferred to it. There may be at most one \texttt{otherwise} statement and its location within the select statement does not matter.

Each statement embedded in the \texttt{when-statement} has its own scope whether or not an explicit block surrounds it.

11.8 The While Do and Do While Loops

There are two variants of the while loop in Chapel. The syntax of the while-do loop is given by:

\textbf{while-do-statement}:

\textbf{while} expression \textbf{do} statement
\textbf{while} expression block-statement

The syntax of the do-while loop is given by:

\textbf{do-while-statement}:

\textbf{do} statement \textbf{while} expression ;

In both variants, the expression evaluates to a value of type \texttt{bool} which determines when the loop terminates and control continues with the statement following the loop.

The while-do loop is executed as follows:

1. The expression is evaluated.
2. If the expression evaluates to \texttt{false}, the statement is not executed and control continues to the statement following the loop.
3. If the expression evaluates to \texttt{true}, the statement is executed and control continues to step 1, evaluating the expression again.
The do-while loop is executed as follows:

1. The statement is executed.
2. The expression is evaluated.
3. If the expression evaluates to false, control continues to the statement following the loop.
4. If the expression evaluates to true, control continues to step 1 and the statement is executed again.

In this second form of the loop, note that the statement is executed unconditionally the first time.

Example (while.chpl). The following example illustrates the difference between the do-while-statement and the while-do-statement. The body of the do-while loop is always executed at least once, even if the loop conditional is already false when it is entered. The code

```chapel
var t = 11;
write("Scope of do while loop:");
do {
  t += 1;
  write(t);
} while (t <= 10);
t = 11;
write("Scope of while loop:");
while (t <= 10) {
  t += 1;
  write(t);
}
```

produces the output

```
Scope of do while loop:
12
Scope of while loop:
```

Chapel do-while loops differ from those found in most other languages in one important regard. If the body of a do-while statement is a block statement and new variables are defined within that block statement, then the scope of those variables extends to cover the loop’s termination expression.

Example (do-while.chpl). The following example demonstrates that the scope of the variable t includes the loop termination expression.

```chapel
var i = 0;
do {
  var t = i;
  i += 1;
  write(t);
} while (t != 5);
```

produces the output

```
0
1
2
3
4
5
```
11.9 The For Loop

The for loop iterates over ranges, domains, arrays, iterators, or any class that implements an iterator named these. The syntax of the for loop is given by:

```
for -statement:
for index-var-declaration in iterable-expression do statement
for index-var-declaration in iterable-expression block-statement
for iterable-expression do statement
for iterable-expression block-statement
```

```
index-var-declaration:
identifier
tuple-grouped-identifier-list
```

```
iteratable-expression:
expression
zip ( expression-list )
```

The `index-var-declaration` declares new variables for the scope of the loop. It may specify a new identifier or may specify multiple identifiers grouped using a tuple notation in order to destructure the values returned by the iterator expression, as described in §14.6.3.

The `index-var-declaration` is optional and may be omitted if the indices do not need to be referenced in the loop.

If the `iteratable-expression` begins with the keyword `zip` followed by a parenthesized expression-list, the listed expressions must support zipper iteration.

11.9.1 Zipper Iteration

When multiple iterators are iterated over in a zipper context, on each iteration, each expression is iterated over, the values are returned by the iterators in a tuple and assigned to the index, and then statement is executed.

The shape of each iterator, the rank and the extents in each dimension, must be identical.

```
Example (zipper.chpl). The output of

```for (i, j) in zip(1..3, 4..6) do
write(i, " ", j, " ");
```

is

```
1 4 2 5 3 6
```
Statements

11.9.2 Parameter For Loops

Parameter for loops are unrolled by the compiler so that the index variable is a parameter rather than a variable. The syntax for a parameter for loop statement is given by:

\[ \text{param--for--statement:} \]
\[ \text{for param identifier in param--iteratable--expression do statement} \]
\[ \text{for param identifier in param--iteratable--expression block--statement} \]

Parameter for loops are restricted to iteration over range literals with an optional by expression where the bounds and stride must be parameters. The loop is then unrolled for each iteration.

11.10 The Break, Continue and Label Statements

The break- and continue-statements are used to alter the flow of control within a loop construct. A break-statement causes flow to exit the containing loop and resume with the statement immediately following it. A continue-statement causes control to jump to the end of the body of the containing loop and resume execution from there. By default, break- and continue-statements exit or skip the body of the immediately-containing loop construct.

The label-statement is used to name a specific loop so that break and continue can exit or resume a less-nested loop. Labels can only be attached to for-, while-do- and do-while-statements. When a break statement has a label, execution continues with the first statement following the loop statement with the matching label. When a continue statement has a label, execution continues at the end of the body of the loop with the matching label. If there is no containing loop construct with a matching label, a compile-time error occurs.

The syntax for label, break, and continue statements is given by:

\[ \text{break--statement:} \]
\[ \text{break identifier} \]
\[ \text{continue--statement:} \]
\[ \text{continue identifier} \]
\[ \text{label--statement:} \]
\[ \text{label identifier statement} \]

Break-statements cannot be used to exit parallel loops.

Rationale. Breaks are not permitted in parallel loops because the execution order of the iterations of parallel loops is not defined.

Future. We expect to support a eureka concept which would enable one or more tasks to stop the execution of all current and future iterations of the loop.
Example. In the following code, the index of the first element in each row of A that is equal to findVal is printed. Once a match is found, the continue statement is executed causing the outer loop to move to the next row.

```plaintext
label outer for i in 1..n {
    for j in 1..n {
        if A[i, j] == findVal {
            writeln("index: ", (i, j), " matches.");
            continue outer;
        }
    }
}
```

11.11 The Use Statement

The use statement makes symbols in each listed module’s scope available from the scope where the use statement occurs. For more information on use statements, see §12.4.4.

11.12 The Empty Statement

An empty statement has no effect. The syntax of an empty statement is given by

```plaintext
empty-statement:
;
```
12 Modules

Chapel supports modules to manage name spaces. A program consists of one or more modules. Every symbol, including variables, functions, and types, is associated with some module.

Module definitions are described in §12.1. The relation between files and modules is described in §12.2. Nested modules are described in §12.3. The visibility of a module’s symbols by users of the module is described in §12.4. The execution of a program and module initialization is described in §12.5.

12.1 Module Definitions

A module is declared with the following syntax:

```
module-declaration-statement:
  privacy-specifier opt module module-identifier block-statement
```

```
privacy-specifier:
  private
  public
```

```
module-identifier:
  identifier
```

A module’s name is specified after the `module` keyword. The `block-statement` opens the module’s scope. Symbols defined in this block statement are defined in the module’s scope and are called top-level module symbols. The visibility of a module is defined by its `privacy-specifier` (§12.4.1).

Module declaration statements must be top-level statements within a module. A module that is declared within another module is called a nested module (§12.3).

12.2 Files and Implicit Modules

Multiple modules can be defined in the same file and need not bear any relation to the file in terms of their names.

Example (two-modules.chpl). The following file contains two explicitly named modules (§12.4.3), MX and MY.

```
module MX {
  var x: string = "Module MX";
  proc printX() {
    writeln(x);
  }
}

module MY {
```

var y: string = "Module MY";
proc printY() {
    writeln(y);
}

Module MX defines top-level module symbols x and printX, while MY defines top-level module symbols y and printY.

For any file that contains top-level statements other than module declarations, the file itself is treated as the module declaration. In this case, the module is implicit and takes its name from the base filename. In particular, the module name is defined as the remaining string after removing the .chpl suffix and any path specification from the specified filename. If the resulting name is not a legal Chapel identifier, it cannot be referenced in a use statement.

Example (implicit.chpl). The following file, named myModule.chpl, defines an implicitly named module called myModule.

var x: int = 0;
var y: int = 1;
proc printX() {
    writeln(x);
}
proc printY() {
    writeln(y);
}

Module myModule defines the top-level module symbols x, y, printX, and printY.

12.3 Nested Modules

A nested module is a module that is defined within another module, the outer module. Nested modules automatically have access to all of the symbols in the outer module. However, the outer module needs to explicitly use a nested module to have access to its symbols.

A nested module can be used without using the outer module by explicitly naming the outer module in the use statement.

Example (nested-use.chpl). The code

use libsci.blas;

uses a module named blas that is nested inside a module named libsci.

Files with both module declarations and top-level statements result in nested modules.

Example (nested.chpl). The following file, named myModule.chpl, defines an implicitly named module called myModule, with nested modules MX and MY.
12.4 Access of Module Contents

A module’s contents can be accessed by code outside of that module depending on the visibility of the module itself (§12.4.1) and the visibility of each individual symbol (§12.4.2). This can be done via explicit naming (§12.4.3) or the use statement (§12.4.4).

12.4.1 Visibility Of A Module

A top-level module is visible anywhere if the privacy-specifier of its declaration is public or is omitted (i.e. by default). A top-level module declared private is visible only within that module. The visibility of a nested module is subject to the rules of §12.4.2. There, the nested module is considered a “symbol defined at the top level scope” of its outer module.

12.4.2 Visibility Of A Module’s Symbols

A symbol defined at the top level scope of a module is visible from outside the module when the privacy-specifier of its definition is public or is omitted (i.e. by default). When a symbol defined at the top level scope of a module is declared private, it is not visible outside of that module. A symbol’s visibility inside its module is controlled by normal lexical scoping and is not affected by its privacy-specifier. A module’s visible symbols are accessible via explicit naming (§12.4.3) or the use statement (§12.4.4) only where the module’s symbol is visible (§12.4.1).

12.4.3 Explicit Naming

All publicly visible top-level module symbols can be named explicitly with the following syntax:
**Module Access Expression:**

- module-access-expression:
  - module-identifier-list . identifier

**Module-Identifier-List:**

- module-identifier
  - module-identifier . module-identifier-list

This allows two variables that have the same name to be distinguished based on the name of their module. Using explicit module naming in a function call restricts the set of candidate functions to those in the specified module.

If code refers to symbols that are defined by multiple modules, the compiler will issue an error. Explicit naming can be used to disambiguate the symbols in this case.

*Open issue.* It is currently unspecified whether the first-named module is always at the outermost module level scope, or whether a scope-search mechanism is used starting at the scope containing the usage.

**Example (ambiguity.chpl).** In the following example,

```plaintext
module M1 {
    var x: int = 1;
    var y: int = -1;
    proc printX() {
        writeln("M1’s x is: ", x);
    }
    proc printY() {
        writeln("M1’s y is: ", y);
    }
}

module M2 {
    use M3;
    use M1;
    var x: int = 2;
    proc printX() {
        writeln("M2’s x is: ", x);
    }
    proc main() {
        M1.x = 4;
        M1.printX();
        writeln(x);
        printX(); // This is not ambiguous
        printY(); // ERROR: This is ambiguous
    }
}

module M3 {
    var x: int = 3;
    var y: int = -3;
    proc printY() {
        writeln("M3’s y is: ", y);
    }
}
```

The call to printX() is not ambiguous because M2’s definition shadows that of M1. On the other hand, the call to printY() is ambiguous because it is defined in both M1 and M3. This will result in a compiler error.
12.4.4 Using Modules

If a module is visible to where accessing its symbols is desirable, then a use statement on that module may be employed. Use statements make a module’s visible symbols available without requiring them to be prefixed by the module’s name. The syntax of the use statement is given by:

```
use-statement:
  use module-name-list;

module-name-list:
  module-name
  module-name , module-name-list

module-name:
  identifier
  module-name . module-name
```

Symbols made available by a use statement are at an outer scope from those defined directly in the scope where the use statement occurs, but at a nearer scope than symbols defined in the scope containing the scope where the use statement occurs.

Use statements are transitive by default: if a module A used by another module B also contains a use of a further module C, C’s symbols will also be considered visible within B, at a further scope than the symbols of other modules immediately used by B.

It is an error for two public variables, types, or modules to be defined at the same depth.

Open issue. There is an expectation that this statement will be extended to allow the programmer to restrict which symbols are ‘used’ as well as to rename symbols that are ‘used.’

Example (use.chpl). The following example illustrates how the use statement makes symbols declared in M1’s scope (like procedure foo()) visible within the scope of M2’s main function. Without the use statement, the procedure call to foo could not be resolved since M2 would not have access to symbols in M1.

When executed, the program

```
module M1 {
  proc foo() {
    writeln("In M1’s foo.");
  }
}

module M2 {
  proc main() {
    use M1;
    writeln("In M2’s main.");
    foo();
  }
}
```

prints out
```
In M2’s main.
In M1’s foo.
```
12.4.5 Module Initialization

Module initialization occurs at program start-up. All top-level statements in a module other than function and type declarations are executed during module initialization.

Example (init.chpl). In the code,

```chapel
var x = foo();  // executed at module initialization
writeln("Hi!");  // executed at module initialization
proc sayGoodbye {
    writeln("Bye!");  // not executed at module initialization
}
```

The function foo() will be invoked and its result assigned to x. Then “Hi!” will be printed.

Module initialization order is discussed in §12.5.2.

12.5 Program Execution

Chapel programs start by initializing all modules and then executing the main function (§12.5.1).

12.5.1 The main Function

The main function must be called main and must have zero arguments. It can be specified with or without parentheses. In any Chapel program, there is a single main function that defines the program’s entry point. If a program defines multiple potential entry points, the implementation may provide a compiler flag that disambiguates between main functions in multiple modules.

Cray’s Chapel Implementation. In the Cray Chapel compiler implementation, the –main-module flag can be used to specify the module from which the main function definition will be used.

Example (main-module.chpl). Because it defines two main functions, the following code will yield an error unless a main module is specified on the command line.

```chapel
module M1 {
    const x = 1;
    proc main() {
        writeln("M", x, ", "s main");
    }
}

module M2 {
    use M1;
    const x = 2;
    proc main() {
        M1.main();
        writeln("M", x, ", "s main");
    }
}
If M1 is specified as the main module, the program will output:

M1’s main

If M2 is specified as the main module the program will output:

M1’s main
M2’s main

Notice that main is treated like just another function if it is not in the main module and can be called as such.

To aid in exploratory programming, a default main function is created if the program does not contain a user-defined main function. The default main function is equivalent to

\[
\text{proc main() \{} \\
\text{\}}
\]

**Example (no-main.chpl)**. The code

\[
\text{writeln("hello, world");}
\]

is a legal and complete Chapel program. The startup code for a Chapel program first calls the module initialization code for the main module and then calls main(). This program’s initialization function is the top-level writeln() statement. The module declaration is taken to be the entire file, as described in §12.2.

### 12.5.2 Module Initialization Order

Module initialization is performed using the following algorithm.

Starting from the module that defines the main function, the modules named in its use statements are visited depth-first and initialized in post-order. If a use statement names a module that has already been visited, it is not visited a second time. Thus, infinite recursion is avoided.

Modules used by a given module are visited in the order in which they appear in the program text. For nested modules, the parent module and its uses are initialized before the nested module and its uses.

**Example (init-order.chpl)**. The code

\[
\text{module M1 \{} \\
\text{ use M2,M3;} \\
\text{ use M2;} \\
\text{ writeln("In M1’s initializer");} \\
\text{ proc main() \{} \\
\text{ writeln("In main");} \\
\text{ \}}
\]

\[
\text{module M2 \{} \\
\text{ use M4;} \\
\text{ writeln("In M2’s initializer");} \\
\text{ module M3 \{} \\
\text{ writeln("In M3’s initializer");} \\
\text{ \}}
\]

```csharp
module M4 {
    writeln("In M4’s initializer");
}
```

prints the following:

- In M4’s initializer
- In M2’s initializer
- In M3’s initializer
- In M1’s initializer
- In main

M1, the main module, uses M2.M3 and then M2, thus M2.M3 must be initialized. Because M2.M3 is a nested module, M4 (which is used by M2) must be initialized first. M2 itself is initialized, followed by M2.M3. Finally M1 is initialized, and the main function is run.
13 Procedures

A function is a code abstraction that can be invoked by a call expression. Throughout this specification the term “function” is used in this programming-languages sense, rather than in the mathematical sense. A function has zero or more formal arguments, or simply formals. Upon a function call each formal is associated with the corresponding actual argument, or simply actual. Actual arguments are provided as part of the call expression, or at the the call site. Direct and indirect recursion is supported.

A function can be a procedure, which completes and returns to the call site exactly once, returning no result, a single result, or multiple results aggregated in a tuple. A function can also be an iterator, which can generate, or yield, multiple results (in sequence and/or in parallel). A function (either a procedure or an iterator) can be a method if it is bound to a type (often a class). An operator in this chapter is a procedure with a special name, which can be invoked using infix notation, i.e., via a unary or binary expression. This chapter defines procedures, but most of its contents apply to iterators and methods as well.

Functions are presented as follows:

- procedures (this chapter)
- operators §13.2 §10.12
- iterators §21
- methods (when bound to a class) §15.1.4
- function calls §13.1
- various aspects of defining a procedure §13.2 §13.10
- calling external functions from Chapel §30.1.1
- calling Chapel functions from external functions §30.1.2
- determining the function to invoke for a given call site: function and operator overloading §13.11 function resolution §13.12

13.1 Function Calls

The syntax to call a non-method function is given by:

```
call-expression:
  lvalue-expression ( named-expression-list )
lvalue-expression [ named-expression-list ]
parenthesesless-function-identifier

named-expression-list:
  named-expression
  named-expression , named-expression-list
```
A call-expression is resolved to a particular function according to the algorithm for function resolution described in §13.12.

Functions can be called using either parentheses or brackets.

Rationale. This provides an opportunity to blur the distinction between an array access and a function call and thereby exploit a possible space/time tradeoff.

Functions that are defined without parentheses must be called without parentheses as defined by scope resolution. Functions without parentheses are discussed in §13.3.

A named-expression is an expression that may be optionally named. It provides an actual argument to the function being called. The optional identifier refers to a named formal argument described in §13.4.1.

Calls to methods are defined in Section §15.5.

### 13.2 Procedure Definitions

Procedures are defined with the following syntax:

```
procedure-declaration-statement:
  privacy-specifier_{opt} linkage-specifier_{opt} proc function-name argument-list_{opt} return-intent_{opt} return-type_{opt} where-clause_{opt} function-body

linkage-specifier:
  inline

function-name:
  identifier
  operator-name

operator-name: one of
  + - * / % ** ! == != >= <= <> << >> & | ^ ~
  += -= *= /= %= **= &= |= ^= <<= >>= <<= >=

argument-list:
  ( formals_{opt} )

formals:
  formal
  formal, formals

formal:
```
Functions do not require parentheses if they have no arguments. Such functions are described in §13.3.

Formal arguments can be grouped together using a tuple notation as described in §14.6.4.

Default expressions allow for the omission of actual arguments at the call site, resulting in the implicit passing of a default value. Default values are discussed in §13.4.2.

The intents const, const in, const ref, in, out, inout and ref are discussed in §13.5. The intents param and type make a function generic and are discussed in §22.1. If the formal argument’s type is omitted, generic, or prefixed with a question mark, the function is also generic and is discussed in §22.1.

Functions can take a variable number of arguments. Such functions are discussed in §13.6.
The return-intent can be used to indicate how the value is returned from a function. return-intent is described further in §13.7.

Open issue. Parameter and type procedures are supported. Parameter and type iterators are currently not supported.

The return-type is optional and is discussed in §13.9. A type function may not specify a return type.

The optional where-clause is only applicable if the function is generic. It is discussed in §22.4.

Function and operator overloading is supported in Chapel and is discussed in §13.11. Operator overloading is supported on the operators listed above (see operator-name).

The optional privacy-specifier keywords indicate the visibility of module level procedures to outside modules. By default, procedures are publicly visible. More details on visibility can be found in §12.4.2.

The linkage specifier inline indicates that the function body must be inlined at every call site.

See the chapter on interoperability (§30) for details on exported and imported functions.

### 13.3 Functions without Parentheses

Functions do not require parentheses if they have empty argument lists. Functions declared without parentheses around empty argument lists must be called without parentheses.

*Example (function-no-parens.chpl).* Given the definitions

```chapel
proc foo { writeln("In foo"); }
proc bar() { writeln("In bar"); }
```

the procedure `foo` can be called by writing `foo` and the procedure `bar` can be called by writing `bar()`. It is an error to use parentheses when calling `foo` or omit them when calling `bar`.

### 13.4 Formal Arguments

A formal argument’s intent (§13.5) specifies how the actual argument is passed to the function. If no intent is specified, the default intent (§13.5.2) is applied, resulting in type-dependent behavior.
13.4.1 Named Arguments

A formal argument can be named at the call site to explicitly map an actual argument to a formal argument.

*Example (named-args.chpl).* Running the code

```chapl
proc foo(x: int, y: int) { writeln(x); writeln(y); }
foo(x=2, y=3);
foo(y=3, x=2);
```

will produce the output

```
2
3
2
3
```

Named argument passing is used to map the actual arguments to the formal arguments. The two function calls are equivalent.

Named arguments are sometimes necessary to disambiguate calls or ignore arguments with default values. For a function that has many arguments, it is sometimes good practice to name the arguments at the call site for compiler-checked documentation.

13.4.2 Default Values

Default values can be specified for a formal argument by appending the assignment operator and a default expression to the declaration of the formal argument. If the actual argument is omitted from the function call, the default expression is evaluated when the function call is made and the evaluated result is passed to the formal argument as if it were passed from the call site.

*Example (default-values.chpl).* The code

```chapl
proc foo(x: int=5, y: int=7) { writeln(x); writeln(y); }
foo();
foo(7);
foo(y=5);
```

writes out

```
5
7
7
7
5
5
```

Default values are specified for the formal arguments x and y. The three calls to `foo` are equivalent to the following three calls where the actual arguments are explicit: `foo(5, 7), foo(7, 7), and foo(5, 5)`. The example `foo(y=5)` shows how to use a named argument for y in order to use the default value for x in the case when x appears earlier than y in the formal argument list.
13.5 Argument Intents

Argument intents specify how an actual argument is passed to a function where it is represented by the corresponding formal argument.

Argument intents are categorized as being either concrete or abstract. Concrete intents are those in which the semantics of the intent keyword are independent of the argument’s type. Abstract intents are those in which the keyword (or lack thereof) expresses a general intention that will ultimately be implemented via one of the concrete intents. The specific choice of concrete intent depends on the argument’s type and may be implementation-defined. Abstract intents are provided to support productivity and code reuse.

13.5.1 Concrete Intents

The concrete intents are \textit{in}, \textit{out}, \textit{inout}, \textit{ref}, \textit{const in}, and \textit{const ref}.

The In Intent

When \textit{in} is specified as the intent, the actual argument is copied into the formal argument when the function is called. An implicit conversion occurs from the actual argument to the type of the formal. The formal can be modified within the function, but such changes are local to the function and not reflected back to the call site.

The Out Intent

When \textit{out} is specified as the intent, the actual argument is ignored when the call is made, but when the function returns, the formal argument is copied back to the actual argument. An implicit conversion occurs from the type of the formal to the type of the actual. The actual argument must be a valid lvalue. The formal argument is initialized to its default value if one is supplied, or to its type’s default value otherwise. The formal argument can be modified within the function.

The Inout Intent

When \textit{inout} is specified as the intent, the actual argument is copied into the formal argument as with the \textit{in} intent and then copied back out as with the \textit{out} intent. The actual argument must be a valid lvalue. The formal argument can be modified within the function. The type of the actual argument must be the same as the type of the formal.

The Ref Intent

When \textit{ref} is specified as the intent, the actual argument is passed by reference. Any reads of, or modifications to, the formal argument are performed directly on the corresponding actual argument at the call site. The actual argument must be a valid lvalue. The type of the actual argument must be the same as the type of the formal.

The \textit{ref} intent differs from the \textit{inout} intent in that the \textit{inout} intent requires copying from/to the actual argument on the way in/out of the function, while \textit{ref} allows direct access to the actual argument through the formal argument without copies. Note that concurrent modifications to the \textit{ref} actual argument by other tasks may be visible within the function, subject to the memory consistency model.
The Const In Intent

The `const in` intent is identical to the `in` intent, except that modifications to the formal argument are prohibited within the function.

The Const Ref Intent

The `const ref` intent is identical to the `ref` intent, except that modifications to the formal argument are prohibited within the dynamic scope of the function. Note that concurrent tasks may modify the actual argument while the function is executing and that these modifications may be visible to reads of the formal argument within the function’s dynamic scope (subject to the memory consistency model).

Summary of Concrete Intents

The following table summarizes the differences between the concrete intents:

<table>
<thead>
<tr>
<th>copied in on function call?</th>
<th>in</th>
<th>out</th>
<th>inout</th>
<th>ref</th>
<th>const in</th>
<th>const ref</th>
</tr>
</thead>
<tbody>
<tr>
<td>copied out on function return?</td>
<td>yes</td>
<td>no</td>
<td>yes</td>
<td>no</td>
<td>yes</td>
<td>no</td>
</tr>
<tr>
<td>refers to actual argument?</td>
<td>no</td>
<td>yes</td>
<td>no</td>
<td>yes</td>
<td>no</td>
<td>yes</td>
</tr>
<tr>
<td>formal can be read?</td>
<td>yes</td>
<td>yes</td>
<td>yes</td>
<td>yes</td>
<td>yes</td>
<td>yes</td>
</tr>
<tr>
<td>formal can be modified?</td>
<td>yes</td>
<td>yes</td>
<td>yes</td>
<td>yes</td>
<td>no</td>
<td>no</td>
</tr>
<tr>
<td>local changes affect the actual?</td>
<td>no</td>
<td>on return</td>
<td>on return</td>
<td>immediately</td>
<td>N/A</td>
<td>N/A</td>
</tr>
</tbody>
</table>

13.5.2 Abstract Intents

The abstract intents are `const` and the `default intent` (when no intent is specified).

The Const Intent

The `const` intent specifies the intention that the function will not and cannot modify the formal argument within its dynamic scope, yet leaves unspecified whether the actual argument will be passed by `const in` or `const ref` intent. In general, small values, such as scalar types, will be passed by `const in`; while larger values, such as domains and arrays, will be passed by `const ref` intent. At present, the decision between the two mechanisms is implementation-defined. If a user’s function is sensitive to which mechanism is used, they should use the desired concrete intent to guarantee portability.

Open issue. It remains an open issue whether the choice between `const in` and `const ref` should be defined by the language, either for certain types or for all of them. One area of active debate is whether the implementation can choose between `const in` and `const ref` for records based on size. Another open issue is how tuples should be handled with respect to `const` intents.
Cray’s Chapel Implementation. The current implementation uses the following mapping:

<table>
<thead>
<tr>
<th>type</th>
<th>meaning of const</th>
</tr>
</thead>
<tbody>
<tr>
<td>bool</td>
<td>const in</td>
</tr>
<tr>
<td>int</td>
<td>const in</td>
</tr>
<tr>
<td>uint</td>
<td>const in</td>
</tr>
<tr>
<td>real</td>
<td>const in</td>
</tr>
<tr>
<td>imag</td>
<td>const in</td>
</tr>
<tr>
<td>complex</td>
<td>const in</td>
</tr>
<tr>
<td>string</td>
<td>const ref</td>
</tr>
<tr>
<td>sync</td>
<td>const ref</td>
</tr>
<tr>
<td>single</td>
<td>const ref</td>
</tr>
<tr>
<td>atomic</td>
<td>const in</td>
</tr>
<tr>
<td>record</td>
<td>const ref</td>
</tr>
<tr>
<td>class</td>
<td>const in</td>
</tr>
<tr>
<td>union</td>
<td>const in</td>
</tr>
<tr>
<td>dmap</td>
<td>const ref</td>
</tr>
<tr>
<td>domain</td>
<td>const ref</td>
</tr>
<tr>
<td>array</td>
<td>const ref</td>
</tr>
</tbody>
</table>

The Default Intent

When no intent is specified for a formal argument, the default intent is applied. It is designed to take the most natural/least surprising action for the argument, based on its type. The following table shows how default intents are interpreted based on the argument’s type:

<table>
<thead>
<tr>
<th>type</th>
<th>meaning of default intent</th>
</tr>
</thead>
<tbody>
<tr>
<td>bool</td>
<td>const</td>
</tr>
<tr>
<td>int</td>
<td>const</td>
</tr>
<tr>
<td>uint</td>
<td>const</td>
</tr>
<tr>
<td>real</td>
<td>const</td>
</tr>
<tr>
<td>imag</td>
<td>const</td>
</tr>
<tr>
<td>complex</td>
<td>const</td>
</tr>
<tr>
<td>string</td>
<td>const</td>
</tr>
<tr>
<td>sync</td>
<td>ref</td>
</tr>
<tr>
<td>single</td>
<td>ref</td>
</tr>
<tr>
<td>atomic</td>
<td>ref</td>
</tr>
<tr>
<td>record</td>
<td>const</td>
</tr>
<tr>
<td>class</td>
<td>const</td>
</tr>
<tr>
<td>union</td>
<td>const</td>
</tr>
<tr>
<td>dmap</td>
<td>const</td>
</tr>
<tr>
<td>domain</td>
<td>const</td>
</tr>
<tr>
<td>array</td>
<td>ref</td>
</tr>
</tbody>
</table>

Open issue. How tuples should be handled under default intents is an open issue; particularly for heterogeneous tuples whose components would fall into separate categories in the table above. One proposed approach is to apply the default intent to each component of the tuple independently.
Another open issue arises if the meaning of the `const` intent is not defined by the language completely. If so, should the meaning of the default intent have that same flexibility? In particular, should the default intent for records mean `const` or `const in`?

### 13.6 Variable Number of Arguments

Functions can be defined to take a variable number of arguments where those arguments can have any intent or can be types. A variable number of parameters is not supported. This allows the call site to pass a different number of actual arguments. There must be at least one actual argument.

If the variable argument expression contains an identifier prepended by a question mark, the number of actual arguments can vary, and the identifier will be bound to an integer parameter value indicating the number of arguments at a given call site. If the variable argument expression contains an expression without a question mark, that expression must evaluate to an integer parameter value requiring the call site to pass that number of arguments to the function.

Within the function, the formal argument that is marked with a variable argument expression is a tuple of the actual arguments.

#### Example (varargs.chpl)

The code

```chapel
proc mywriteln(x ...?k) {
    for param i in 1..k do
        writeln(x(i));
}
```

defines a generic procedure called `mywriteln` that takes a variable number of arguments of any type and then writes them out on separate lines. The parameter for-loop (§11.9.2) is unrolled by the compiler so that `i` is a parameter, rather than a variable. This needs to be a parameter for-loop because the expression `x(i)` will have a different type on each iteration. The type of `x` can be specified in the formal argument list to ensure that the actuals all have the same type.

#### Example (varargs-with-type.chpl)

Either or both the number of variable arguments and their types can be specified. For example, a basic procedure to sum the values of three integers can be written as

```chapel
proc sum(x: int...3) return x(1) + x(2) + x(3);
```

Specifying the type is useful if it is important that each argument have the same type. Specifying the number is useful in, for example, defining a method on a class that is instantiated over a rank parameter.

#### Example (varargs-returns-tuples.chpl)

The code

```chapel
proc tuple(x ...) return x;
```

defines a generic procedure that is equivalent to building a tuple. Therefore the expressions `tuple(1, 2)` and `(1,2)` are equivalent, as are the expressions `tuple(1)` and `(1,)`.

### 13.7 Return Intents

The `return-intent` specifies how the value is returned from a function, and in what contexts that function is allowed to be used. By default, or if the `return-intent` is `const`, the function returns a value that cannot be used as an lvalue.
13.7.1 The Ref Return Intent

When using a ref return intent, the function call is an lvalue (specifically, a call expression for a procedure and an iterator variable for an iterator). This implies that the function produces a reference; however, this reference cannot be captured.

The ref return intent is specified by following the argument list with the ref keyword. The function must return or yield an lvalue.

When a procedure with a ref return intent is called on the left-hand side of an assignment statement or in the context of a call to a formal argument by out, inout, or ref intent, the lvalue that is returned by the procedure is assigned a value.

Functions with a ref return intent provide an implicit param formal argument setter of type bool. If the function is called in a context requiring an lvalue, the actual argument for setter is implicitly true; otherwise it is false. This argument is useful for adjusting the behavior depending to the calling context.

Example (ref-return-intent.chpl). The following code defines a procedure that can be interpreted as a simple two-element array where the elements are actually module level variables:

```chapl
var x, y = 0;
proc A(i: int) ref {
  if i < 0 || i > 1 then
    halt("array access out of bounds");
  if i == 0 then
    return x;
  else
    return y;
}
```

Calls to this procedure can be assigned to in order to write to the “elements” of the array as in

```
A(0) = 1;
A(1) = 2;
```

It can be called as an expression to access the “elements” as in

```
writeln(A(0) + A(1));
```

This code outputs the number 3.

The implicit setter argument can be used to ensure, for example, that the second element in the pseudo-array is only assigned a value if the first argument is positive. To do this, add the following:

```
if setter && i == 1 && x <= 0 then
  halt("cannot assign value to A(1) if A(0) <= 0");
```

13.7.2 The Param Return Intent

A parameter function, or a param function, is a function that returns a parameter expression. It is specified by following the function’s argument list by the keyword param. It is often, but not necessarily, generic.

It is a compile-time error if a parameter function does not return a parameter expression. The result of a parameter function is computed during compilation and substituted for the call expression.
Example (param-functions.chpl). In the code

```chpl
proc sumOfSquares(param a: int, param b: int) param
  return a**2 + b**2;
var x: sumOfSquares(2, 3)*int;
```

`sumOfSquares` is a parameter procedure that takes two parameters as arguments. Calls to this procedure can be used in places where a parameter expression is required. In this example, the call is used in the declaration of a homogeneous tuple and so is required to be a parameter.

Parameter functions may not contain control flow that is not resolved at compile-time. This includes loops other than the parameter for loop §11.9.2 and conditionals with a conditional expressions that is not a parameter.

### 13.7.3 The Type Return Intent

A type function is a function that returns a type, not a value. It is specified by following the function’s argument list by the keyword `type`, without the subsequent return type. It is often, but not necessarily, generic.

It is a compile-time error if a type function does not return a type. The result of a type function is computed during compilation.

As with parameter functions, type functions may not contain control flow that is not resolved at compile-time. This includes loops other than the parameter for loop §11.9.2 and conditionals with a conditional expression that is not a parameter.

Example (type-functions.chpl). In the code

```chpl
proc myType(x) type {
  if numBits(x.type) <= 32 then return int(32);
  else return int(64);
}
```

`myType` is a type procedure that takes a single argument `x` and returns `int(32)` if the number of bits used to represent `x` is less than or equal to 32, otherwise it returns `int(64)`. `numBits` is a param procedure defined in the standard Types module.

### 13.8 The Return Statement

The return statement can only appear in a function. It causes control to exit that function, returning it to the point at which that function was called.

A procedure can return a value by executing a return statement that includes an expression. If it does, that expression’s value becomes the value of the invoking call expression.

A return statement in a procedure of a non-void return type §13.9 must include an expression. A return statement in a procedure of a void return type or in an iterator must not include an expression. A return statement of a variable procedure must contain an lvalue expression.

The syntax of the return statement is given by
return-statement:
    return expressionopt ;

Example (return.chpl). The following code defines a procedure that returns the sum of three integers:

```
proc sum(i1: int, i2: int, i3: int)
    return i1 + i2 + i3;
```

13.9 Return Types

Every procedure has a return type. The return type is either specified explicitly via return-type in the procedure declaration, or is inferred implicitly.

13.9.1 Explicit Return Types

If a return type is specified and is not void, each return statement of the procedure must include an expression. For a non-ref return intent, an implicit conversion occurs from each return expression to the specified return type. For a ref return intent (§13.7.1), the return type must match the type returned in all of the return statements exactly, when checked after generic instantiation and parameter folding (if applicable).

13.9.2 Implicit Return Types

If a return type is not specified, it is inferred from the return statements. It is illegal for a procedure to have a return statement with an expression and a return statement without an expression. For procedures without any return statements, or when none of the return statements include an expression, the return type is void.

Otherwise, the types of the expressions in all of the procedure’s return statements are considered. If a function has a ref return intent (§13.7.1), they all must be the same exact type, which becomes the inferred return type. Otherwise, there must exist exactly one type such that an implicit conversion is allowed between every other type and that type, and that type becomes the inferred return type. If the above requirements are not satisfied, it is an error.

13.10 Nested Functions

A function defined in another function is called a nested function. Nesting of functions may be done to arbitrary degrees, i.e., a function can be nested in a nested function.

Nested functions are only visible to function calls within the lexical scope in which they are defined.

Nested functions may refer to variables defined in the function(s) in which they are nested.
13.11 Function and Operator Overloading

Functions that have the same name but different argument lists are called overloaded functions. Function calls to overloaded functions are resolved according to the function resolution algorithm in §13.12.

Operator overloading is achieved by defining a function with a name specified by that operator. The operators that may be overloaded are listed in the following table:

<table>
<thead>
<tr>
<th>arity</th>
<th>operators</th>
</tr>
</thead>
<tbody>
<tr>
<td>unary</td>
<td>+ - ! ~</td>
</tr>
<tr>
<td>binary</td>
<td>+ - * / % ** == &lt; &gt; &lt;&lt; &gt;&gt; &amp; ^ by</td>
</tr>
<tr>
<td></td>
<td>+= -= *= /= %= *= &amp;=</td>
</tr>
</tbody>
</table>

The arity and precedence of the operator must be maintained when it is overloaded. Operator resolution follows the same algorithm as function resolution.

13.12 Function Resolution

*Function resolution* is the algorithm that determines which function to invoke for a given call expression. Function resolution is defined as follows.

- Identify the set of visible functions for the function call. A *visible function* is any function that satisfies the criteria in §13.12.1. If no visible function can be found, the compiler will issue an error stating that the call cannot be resolved.

- From the set of visible functions for the function call, determine the set of candidate functions for the function call. A *candidate function* is any function that satisfies the criteria in §13.12.2. If no candidate function can be found, the compiler will issue an error stating that the call cannot be resolved. If exactly one candidate function is found, this is determined to be the function.

- From the set of candidate functions, the most specific function is determined. The most specific function is a candidate function that is more specific than every other candidate function as defined in §13.12.3. If there is no function that is more specific than every other candidate function, the compiler will issue an error stating that the call is ambiguous.

13.12.1 Determining Visible Functions

Given a function call, a function is determined to be a *visible function* if the name of the function is the same as the name of the function call and the function is defined in the same scope as the function call or a lexical outer scope of the function call, or if the function is publicly declared in a module that is used from the same scope as the function call or a lexical outer scope of the function call. Function visibility in generic functions is discussed in §22.2.
13.12.2 Determining Candidate Functions

Given a function call, a function is determined to be a candidate function if there is a valid mapping from the function call to the function and each actual argument is mapped to a formal argument that is a legal argument mapping.

Valid Mapping

The following algorithm determines a valid mapping from a function call to a function if one exists:

- Each actual argument that is passed by name is matched to the formal argument with that name. If there is no formal argument with that name, there is no valid mapping.
- The remaining actual arguments are mapped in order to the remaining formal arguments in order. If there are more actual arguments then formal arguments, there is no valid mapping. If any formal argument that is not mapped to by an actual argument does not have a default value, there is no valid mapping.
- The valid mapping is the mapping of actual arguments to formal arguments plus default values to formal arguments that are not mapped to by actual arguments.

Legal Argument Mapping

An actual argument of type $T_A$ can be mapped to a formal argument of type $T_F$ if any of the following conditions hold:

- $T_A$ and $T_F$ are the same type.
- There is an implicit conversion from $T_A$ to $T_F$.
- $T_A$ is derived from $T_F$.
- $T_A$ is scalar promotable to $T_F$.

13.12.3 Determining More Specific Functions

Given two functions $F_1$ and $F_2$, the more specific function is determined by the following steps:

- If $F_1$ does not require promotion and $F_2$ does require promotion, then $F_1$ is more specific.
- If $F_2$ does not require promotion and $F_1$ does require promotion, then $F_2$ is more specific.
- If at least one of the legal argument mappings to $F_1$ is a more specific argument mapping than the corresponding legal argument mapping to $F_2$ and none of the legal argument mappings to $F_2$ is a more specific argument mapping than the corresponding legal argument mapping to $F_1$, then $F_1$ is more specific.
- If at least one of the legal argument mappings to $F_2$ is a more specific argument mapping than the corresponding legal argument mapping to $F_1$ and none of the legal argument mappings to $F_1$ is a more specific argument mapping than the corresponding legal argument mapping to $F_2$, then $F_2$ is more specific.
• If \( F_1 \) shadows \( F_2 \), then \( F_1 \) is more specific.
• If \( F_2 \) shadows \( F_1 \), then \( F_2 \) is more specific.
• If all \texttt{param} arguments prefer \( F_1 \) over \( F_2 \), then \( F_1 \) is more specific. In order of preference, a \texttt{param} argument prefers to passed to (a) a \texttt{param} formal of matching type; (b) a \texttt{param} formal large enough to store the \texttt{param} value; (c) a non-\texttt{param} formal of matching type.
• If all \texttt{param} arguments prefer \( F_2 \) over \( F_1 \), then \( F_2 \) is more specific.
• If \( F_1 \) has a where clause and \( F_2 \) does not have a where clause, then \( F_1 \) is more specific.
• If \( F_2 \) has a where clause and \( F_1 \) does not have a where clause, then \( F_2 \) is more specific.
• Otherwise neither function is more specific.

Given an argument mapping, \( M_1 \), from an actual argument, \( A \), of type \( T_A \) to a formal argument, \( F_1 \), of type \( T_{F_1} \) and an argument mapping, \( M_2 \), from the same actual argument to a formal argument, \( F_2 \), of type \( T_{F_2} \), the more specific argument mapping is determined by the following steps:

• If \( T_{F_1} \) and \( T_{F_2} \) are the same type, \( F_1 \) is an instantiated parameter, and \( F_2 \) is not an instantiated parameter, \( M_1 \) is more specific.
• If \( T_{F_1} \) and \( T_{F_2} \) are the same type, \( F_2 \) is an instantiated parameter, and \( F_1 \) is not an instantiated parameter, \( M_2 \) is more specific.
• If \( M_1 \) does not require scalar promotion and \( M_2 \) requires scalar promotion, \( M_1 \) is more specific.
• If \( M_1 \) requires scalar promotion and \( M_2 \) does not require scalar promotion, \( M_2 \) is more specific.
• If \( T_{F_1} \) and \( T_{F_2} \) are the same type, \( F_1 \) is generic, and \( F_2 \) is not generic, \( M_1 \) is more specific.
• If \( T_{F_1} \) and \( T_{F_2} \) are the same type, \( F_2 \) is generic, and \( F_1 \) is not generic, \( M_2 \) is more specific.
• If \( F_1 \) is not generic over all types and \( F_2 \) is generic over all types, \( M_1 \) is more specific.
• If \( F_1 \) is generic over all types and \( F_2 \) is not generic over all types, \( M_2 \) is more specific.
• If \( T_A \) and \( T_{F_1} \) are the same type and \( T_A \) and \( T_{F_2} \) are not the same type, \( M_1 \) is more specific.
• If \( T_A \) and \( T_{F_1} \) are not the same type and \( T_A \) and \( T_{F_2} \) are the same type, \( M_2 \) is more specific.
• If \( T_{F_1} \) is derived from \( T_{F_2} \), then \( M_1 \) is more specific.
• If \( T_{F_2} \) is derived from \( T_{F_1} \), then \( M_2 \) is more specific.
• If there is an implicit conversion from \( T_{F_1} \) to \( T_{F_2} \), then \( M_1 \) is more specific.
• If there is an implicit conversion from \( T_{F_2} \) to \( T_{F_1} \), then \( M_2 \) is more specific.
• If \( T_{F_1} \) is any \texttt{int} type and \( T_{F_2} \) is any \texttt{uint} type, \( M_1 \) is more specific.
• If \( T_{F_2} \) is any \texttt{int} type and \( T_{F_1} \) is any \texttt{uint} type, \( M_2 \) is more specific.
• Otherwise neither mapping is more specific.
14 Tuples

A tuple is an ordered set of components that allows for the specification of a light-weight collection of values. As the examples in this chapter illustrate, tuples are a boon to the Chapel programmer. In addition to making it easy to return multiple values from a function, tuples help to support multidimensional indices, to group arguments to functions, and to specify mathematical concepts.

14.1 Tuple Types

A tuple type is defined by a fixed number (a compile-time constant) of component types. It can be specified by a parenthesized, comma-separated list of types. The number of types in the list defines the size of the tuple; the types themselves specify the component types.

The syntax of a tuple type is given by:

```
tuple-type: (type-specifier, type-list)
type-list: type-specifier type-specifier, type-list
```

A homogeneous tuple is a special-case of a general tuple where the types of the components are identical. Homogeneous tuples have fewer restrictions for how they can be indexed ([14.3]). Homogeneous tuple types can be defined using the above syntax, or they can be defined as a product of an integral parameter (a compile-time constant integer) and a type. This latter specification is implemented by overloading `*` with the following prototype:

```
proc * (param p: int, type t) type
```

**Rationale.** Homogeneous tuples require the size to be specified as a parameter (a compile-time constant). This avoids any overhead associated with storing the runtime size in the tuple. It also avoids the question as to whether a non-parameter size should be part of the type of the tuple. If a programmer requires a non-parameter value to define a data structure, an array may be a better choice.

**Example (homogenous.chpl).** The statement

```
var x1: (string, real),
   x2: (int, int, int),
   x3: 3*int;
```

defines three variables. Variable `x1` is a 2-tuple with component types `string` and `real`. Variables `x2` and `x3` are homogeneous 3-tuples with component type `int`. The types of `x2` and `x3` are identical even though they are specified in different ways.

Note that if a single type is delimited by parentheses, the parentheses only impact precedence. Thus `(int)` is equivalent to `int`. Nevertheless, tuple types with a single component type are legal and useful. One way to specify a 1-tuple is to use the overloaded `*` operator since every 1-tuple is trivially a homogeneous tuple.
Rationale. Like parentheses around expressions, parentheses around types are necessary for grouping in order to avoid the default precedence of the grammar. Thus it is not the case that we would always want to create a tuple. The type \(3*(3*\text{int})\) specifies a 3-tuple of 3-tuples of integers rather than a 3-tuple of 1-tuples of 3-tuples of integers. The type \(3*3*\text{int}\), on the other hand, specifies a 9-tuple of integers.

### 14.2 Tuple Values

A value of a tuple type attaches a value to each component type. Tuple values can be specified by a parenthesized, comma-separated list of expressions. The number of expressions in the list defines the size of the tuple; the types of these expressions specify the component types of the tuple.

The syntax of a tuple expression is given by:

\[
\text{tuple-expression}:
    \ ( \text{tuple-component,} \ )
\]
\[
\ ( \text{tuple-component, tuple-component-list} \ )
\]

\[
\text{tuple-component}:
    \text{expression}
\]
\[
\ -
\]

\[
\text{tuple-component-list}:
    \text{tuple-component}
\]
\[
\text{tuple-component, tuple-component-list}
\]

An underscore can be used to omit components when splitting a tuple (see [14.6.1]).

**Example (values.chpl)**. The statement

\[
\text{var } x1: (\text{string, real}) = ("hello", 3.14),
\]

\[
\text{x2: (int, int, int) = (1, 2, 3),}
\]

\[
\text{x3: 3*int = (4, 5, 6);}
\]

defines three tuple variables. Variable \(x1\) is a 2-tuple with component types \text{string} and \text{real}. It is initialized such that the first component is "hello" and the second component is 3.14. Variables \(x2\) and \(x3\) are homogeneous 3-tuples with component type \text{int}. Their initialization expressions specify 3-tuples of integers.

Note that if a single expression is delimited by parentheses, the parentheses only impact precedence. Thus \((1)\) is equivalent to 1. To specify a 1-tuple, use the form with the trailing comma \((1,)\).

**Example (onetuple.chpl)**. The statement

\[
\text{var } x: 1*\text{int} = (7,);
\]

creates a 1-tuple of integers storing the value 7.

Tuple expressions are evaluated similarly to function calls where the arguments are all generic with no explicit intent. So a tuple expression containing an array does not copy the array.

When a tuple is passed as an argument to a function, it is passed as if it is a record type containing fields of the same type and in the same order as in the tuple.
14.3 Tuple Indexing

A tuple component may be accessed by an integral parameter (a compile-time constant) as if the tuple were an array. Indexing is 1-based, so the first component in the tuple is accessed by the index 1, and so forth.

Example (access.chpl). The loop

```chpl
var myTuple = (1, 2.0, "three");
for param i in 1..3 do
    writeln(myTuple(i));
```

uses a param loop to output the components of a tuple.

Homogeneous tuples may be accessed by integral values that are not necessarily compile-time constants.

Example (access-homogeneous.chpl). The loop

```chpl
var myHTuple = (1, 2, 3);
for i in 1..3 do
    writeln(myHTuple(i));
```

uses a serial loop to output the components of a homogeneous tuple. Since the index is not a compile-time constant, this would result in an error were tuple not homogeneous.

Rationale. Non-homogeneous tuples can only be accessed by compile-time constants since the type of an expression must be statically known.

14.4 Iteration over Tuples

Only homogenous tuples support iteration via standard for, forall and coforall loops. These loops iterate over all of the tuple’s elements. A loop of the form:

```chpl
[for|forall|coforall] e in t do
    ...e...
```

where t is a homogenous tuple of size n, is semantically equivalent to:

```chpl
[for|forall|coforall] i in 1..n do
    ...t(i)...
```

The iterator variable for an tuple iteration is a either a const value or a reference to the tuple element type, following default intent semantics.

14.5 Tuple Assignment

In tuple assignment, the components of the tuple on the left-hand side of the assignment operator are each assigned the components of the tuple on the right-hand side of the assignment. These assignments occur in component order (component one followed by component two, etc.).
14.6 Tuple Destructuring

Tuples can be split into their components in the following ways:

- In assignment where multiple expression on the left-hand side of the assignment operator are grouped using tuple notation.
- In variable declarations where multiple variables in a declaration are grouped using tuple notation.
- In for, forall, and coforall loops (statements and expressions) where multiple indices in a loop are grouped using tuple notation.
- In function calls where multiple formal arguments in a function declaration are grouped using tuple notation.
- In an expression context that accepts a comma-separated list of expressions where a tuple expression is expanded in place using the tuple expansion expression.

14.6.1 Splitting a Tuple with Assignment

When multiple expression on the left-hand side of an assignment operator are grouped using tuple notation, the tuple on the right-hand side is split into its components. The number of grouped expressions must be equal to the size of the tuple on the right-hand side. In addition to the usual assignment evaluation order of left to right, the assignment is evaluated in component order.

Example (splitting.chpl) The code

```chapel
var a, b, c: int;
(a, (b, c)) = (1, (2, 3));
```

defines three integer variables a, b, and c. The second line then splits the tuple (1, (2, 3)) such that 1 is assigned to a, 2 is assigned to b, and 3 is assigned to c.

Example (aliasing.chpl) The code

```chapel
var A = [i in 1..4] i;
writeln(A);
(A(1..2), A(3..4)) = (A(3..4), A(1..2));
writeln(A);
```

creates a non-distributed, one-dimensional array containing the four integers from 1 to 4. Line 2 outputs 1 2 3 4. Line 3 does what appears to be a swap of array slices. However, because the tuple is created with array aliases (like a function call), the assignment to the second component uses the values just overwritten in the assignment to the first component. Line 4 outputs 3 4 3 4.

When splitting a tuple with assignment, the underscore token can be used to omit storing some of the components. In this case, the full expression on the right-hand side of the assignment operator is evaluated, but the omitted values will not be assigned to anything.

Example (omit-component.chpl) The code

```chapel
```
defines a function that returns a 2-tuple, declares an integer variable $x$, calls the function, assigns the first
component in the returned tuple to $x$, and ignores the second component in the returned tuple. The value
of $x$ becomes 1.

14.6.2 Splitting a Tuple in a Declaration

When multiple variables in a declaration are grouped using tuple notation, the tuple initialization expression is split into
its type and/or value components. The number of grouped variables must be equal to the size of the tuple initialization
expression. The variables are initialized in component order.

The syntax of grouped variable declarations is defined in §8.1.

Example (decl.chpl). The code

```chapel
var (a, (b, c)) = (1, (2, 3));
```

defines three integer variables $a$, $b$, and $c$. It splits the tuple $(1, (2, 3))$ such that 1 initializes $a$, 2
initializes $b$, and 3 initializes $c$.

Grouping variable declarations using tuple notation allows a 1-tuple to be destructured by enclosing a single variable
declaration in parentheses.

Example (onetuple-destruct.chpl). The code

```chapel
var (a) = (1, );
```

initialize the new variable $a$ to 1.

When splitting a tuple into multiple variable declarations, the underscore token may be used to omit components of the
tuple rather than declaring a new variable for them. In this case, no variables are defined for the omitted components.

Example (omit-component-decl.chpl). The code

```chapel
proc f()
    return (1, 2);
var (x, _) = f();
```

defines a function that returns a 2-tuple, calls the function, declares and initializes variable $x$ to the first
component in the returned tuple, and ignores the second component in the returned tuple. The value of $x$
is initialized to 1.
14.6.3 Splitting a Tuple into Multiple Indices of a Loop

When multiple indices in a loop are grouped using tuple notation, the tuple returned by the iterator (§21) is split across the index tuple’s components. The number of indices in the index tuple must equal the size of the tuple returned by the iterator.

Example (indices.chpl). The code

```chapel
iter bar() {
    yield (1, 1);
    yield (2, 2);
}

for (i,j) in bar() do
    writeln(i+j);
```

defines a simple iterator that yields two 2-tuples before completing. The for-loop uses a tuple notation to group two indices that take their values from the iterator.

When a tuple is split across an index tuple, indices in the index tuple (left-hand side) may be omitted. In this case, no indices are defined for the omitted components.

However even when indices are omitted, the iterator is evaluated as if an index were defined. Execution proceeds as if the omitted indices are present but invisible. This means that the loop body controlled by the iterator may be executed multiple times with the same set of (visible) indices.

14.6.4 Splitting a Tuple into Multiple Formal Arguments in a Function Call

When multiple formal arguments in a function declaration are grouped using tuple notation, the actual expression is split into its components during a function call. The number of grouped formal arguments must be equal to the size of the actual tuple expression. The actual arguments are passed in component order to the formal arguments.

The syntax of grouped formal arguments is defined in §13.2.

Example (formals.chpl). The function

```chapel
proc f(x; int, (y, z): (int, int)) {
    // body
}
```

is defined to take an integer value and a 2-tuple of integer values. The 2-tuple is split when the function is called into two formals. A call may look like the following:

```chapel
f(1, (2, 3));
```

An implicit where clause is created when arguments are grouped using tuple notation, to ensure that the function is called with an actual tuple of the correct size. Arguments grouped in tuples may be nested arbitrarily. Functions with arguments grouped into tuples may not be called using named-argument passing on the tuple-grouped arguments. In addition, tuple-grouped arguments may not be specified individually with types or default values (only in aggregate). They may not be specified with any qualifier appearing before the group of arguments (or individual arguments) such as inout or type. They may not be followed by . . . to indicate that there are a variable number of them.
**Example (implicit-where.chpl).** The function \( f \) defined as

```chapel
proc f((x, (y, z))) {
    writeln((x, y, z));
}
```

is equivalent to the function \( g \) defined as

```chapel
proc g(t) where isTuple(t) && t.size == 2 && isTuple(t(2)) && t(2).size == 2 {
    writeln((t(1), t(2)(1), t(2)(2)));
}
```

except without the definition of the argument name \( t \).

Grouping formal arguments using tuple notation allows a 1-tuple to be destructured by enclosing a single formal argument in parentheses.

**Example (grouping-Formals.chpl).** The empty function

```chapel
proc f((x)) {}
```

accepts a 1-tuple actual with any component type.

When splitting a tuple into multiple formal arguments, the arguments that are grouped using the tuple notation may be omitted. In this case, no names are associated with the omitted components. The call is evaluated as if an argument were defined.

### 14.6.5 Splitting a Tuple via Tuple Expansion

Tuples can be expanded in place using the following syntax:

```
tuple-expand-expression:
    ( ... expression )
```

In this expression, the tuple defined by `expression` is expanded in place to represent its components. This can only be used in a context where a comma-separated list of components is valid.

**Example (expansion.chpl).** Given two 2-tuples

```chapel
var x1 = (1, 2.0), x2 = ("three", "four");
```

the following statement

```chapel
var x3 = ((...x1), (...x2));
```

creates the 4-tuple \( x3 \) with the value \((1, 2.0, "three", "four")\).

**Example (expansion-2.chpl).** The following code defines two functions, a function `first` that returns the first component of a tuple and a function `rest` that returns a tuple containing all of the components of a tuple except for the first:

```chapel
proc first(t) where isTuple(t) {
    return t(1);
}
proc rest(t) where isTuple(t) {
    proc helper(first, rest...) {
        return rest;
        return helper((...t));
    }
    return helper((...t));
}
```
14.7 Tuple Operators

14.7.1 Unary Operators

The unary operators +, -, ~, and ! are overloaded on tuples by applying the operator to each argument component and returning the results as a new tuple.

The size of the result tuple is the same as the size of the argument tuple. The type of each result component is the result type of the operator when applied to the corresponding argument component.

The type of every element of the operand tuple must have a well-defined operator matching the unary operator being applied. That is, if the element type is a user-defined type, it must supply an overloaded definition for the unary operator being used. Otherwise, a compile-time error will be issued.

14.7.2 Binary Operators

The binary operators +, -, *, /, %, **, &, |, ^, <<, and >> are overloaded on tuples by applying them to pairs of the respective argument components and returning the results as a new tuple. The sizes of the two argument tuples must be the same. These operators are also defined for homogenous tuples and scalar values of matching type.

The size of the result tuple is the same as the argument tuple(s). The type of each result component is the result type of the operator when applied to the corresponding pair of the argument components.

When a tuple binary operator is used, the same operator must be well-defined for successive pairs of operands in the two tuples. Otherwise, the operation is illegal and a compile-time error will result.

Example (binary-ops.chpl). The code

```chapel
var x = (1, 1, 1) + (2, 2.0, "2");
```

creates a 3-tuple of an int, a real and a string with the value (3, 3.0, "12").

14.7.3 Relational Operators

The relational operators >, >=, <, <=, ==, and != are defined over tuples of matching size. They return a single boolean value indicating whether the two arguments satisfy the corresponding relation.

The operators >, >=, <, and <= check the corresponding lexicographical order based on pair-wise comparisons between the argument tuples’ components. The operators == and != check whether the two arguments are pair-wise equal or not. The relational operators on tuples may be short-circuiting, i.e. they may execute only the pair-wise comparisons that are necessary to determine the result.

However, just as for other binary tuple operators, the corresponding operation must be well-defined on each successive pair of operand types in the two operand tuples. Otherwise, a compile-time error will result.

Example (relational-ops.chpl). The code
var x = (1, 1, 0) > (1, 0, 1);

creates a variable initialized to true. After comparing the first components and determining they are equal, the second components are compared to determine that the first tuple is greater than the second tuple.

14.8 Predefined Functions and Methods on Tuples

proc isHomogeneousTuple(t: Tuple) param
    Returns true if t is a homogeneous tuple; otherwise false.

proc isTuple(t: Tuple) param
    Returns true if t is a tuple; otherwise false.

proc isTupleType(type t) param
    Returns true if t is a tuple of types; otherwise false.

proc max(type t) where isTupleType(t)
    Returns a tuple of type t with each component set to the maximum value that can be stored in its position.

proc min(type t) where isTupleType(t)
    Returns a tuple of type t with each component set to the minimum value that can be stored in its position.

proc Tuple.size param
    Returns the size of the tuple.
15 Classes

Classes are data structures with associated state and functions. Storage for a class instance, or object, is allocated independently of the scope of the variable that refers to it. An object is created by calling a class constructor (§15.3), which allocates storage, initializes it, and returns a reference to the newly-created object. Storage can be reclaimed by deleting the object (§15.9).

A class declaration (§15.1) generates a class type (§15.1.1). A variable of a class type can refer to an instance of that class or any of its derived classes.

A class is generic if it has generic fields. Generic classes and fields are discussed in §22.3.

15.1 Class Declarations

A class is defined with the following syntax:

```
class-declaration-statement:
  simple-class-declaration-statement
  external-class-declaration-statement

simple-class-declaration-statement:
  class identifier class-inherit-listopt { class-statement-listopt }

class-inherit-list:
  : class-type-list

class-type-list:
  class-type
  class-type, class-type-list

class-statement-list:
  class-statement
  class-statement class-statement-list

class-statement:
  variable-declaration-statement
  method-declaration-statement
  type-declaration-statement
  empty-statement
```

A class-declaration-statement defines a new type symbol specified by the identifier. Classes inherit data and functionality from other classes if the inherit-type-list is specified. Inheritance is described in §15.2.

Future. Record inheritance is not currently implemented. When enabled, it will have the same effect as creating a field of that record type within the class, except that all of the record’s field and method names will appear within the scope of the inheriting class.
The body of a class declaration consists of a sequence of statements where each of the statements either defines a variable (called a field), a procedure or iterator (called a method), or a type alias. In addition, empty statements are allowed in class declarations, and they have no effect.

If a class declaration contains a type alias or a parameter field, or it contains a variable or constant without a specified type and without an initialization expression, then it declares a generic class type. Generic classes are described in §22.3.

If the `extern` keyword appears before the `class` keyword, then an external class type is declared. An external class type declaration must not contain a `class-inherit-list`. An external class is used within Chapel for type and field resolution, but no corresponding backend definition is generated. It is presumed that the definition of an external class is supplied by a library or the execution environment. See the chapter on interoperability (§30) for more information on external classes.

**Future.** Privacy controls for classes and records are currently not specified, as discussion is needed regarding its impact on inheritance, for instance.

### 15.1.1 Class Types

A class type is given simply by the class name for non-generic classes. Generic classes must be instantiated to serve as a fully-specified type, for example to declare a variable. This is done with type constructors, which are defined in Section 22.3.4.

```
class-type:  
  identifier  
  identifier ( named-expression-list )
```

A class type may appear in inheritance lists of other class declarations.

### 15.1.2 Class Values

A class value is either a reference to an instance of a class or `nil` (§15.2.7). Class instances can be created using the `new` operator (§15.3) and deleted using the `delete` operator (§15.9).

For a given class type, a legal value of that type is a reference to an instance of either that class or a class inheriting, directly or indirectly, from that class. `nil` is a legal value of any class type.

The default value of a class type is `nil`.

**Example (declaration.chpl).**

```chapel
class C { }
var c : C; // c has the class type C, initialized with the value nil.
c = new C(); // Now c refers to an object of type C.
var c2 = c; // The type of c2 is also C.
  // c2 refers to the same object as c.
class D : C {} // Class D is derived from C.
c = new D(); // Now c refers to an object of type D.
```
When the variable \( c \) is declared, it initially has the value of \( \text{nil} \). The next statement assigned to it an instance of the class \( C \). The declaration of variable \( c2 \) shows that these steps can be combined. The type of \( c2 \) is also \( C \), determined implicitly from the the initialization expression. Finally, an object of type \( D \) is created and assigned to \( c \). The object previously referenced by \( c \) is no longer referenced anywhere. It could be reclaimed by the garbage collector.

### 15.1.3 Class Fields

Variable declarations within a class declaration define fields within that class. Parameter fields make a class generic. Variable fields define the storage associated with a class instance.

**Example (defineActor.chpl).** The code

```chpl
class Actor {
    var name: string;
    var age: uint;
}
```

defines a new class type called \( \text{Actor} \) that has two fields: the string field \( \text{name} \) and the unsigned integer field \( \text{age} \).

Field access is described in §15.4.

### 15.1.4 Class Methods

A **method** is a procedure or iterator that is associated with a type known as the **receiver**. Methods on classes are referred to as to as **class methods**. Methods may be defined on other types as well.

Methods are declared with the following syntax:

```chpl
type-binding opt

Class declaration:

```
method-declaration statement:

linkage-boundary declarator proc-or-iter this-intent opt
type-binding opt
function name argument-list opt
return-intent opt
return type opt
where-clause opt
function-body
```

proc-or-iter:

```chpl
proc
iter
```

this-intent:

```chpl
param ref

type
```

Methods defined within the lexical scope of a class, record, or union are referred to as **primary methods**. For such methods, the **type-binding** can be omitted and is taken to be the innermost class, record, or union in which the method is defined. Methods defined outside of such scopes are known as **secondary methods** and must have a **type-binding**
(otherwise, they would simply be standalone functions rather than methods). Note that secondary methods can be defined not only for classes, records, and unions, but also for any other type (e.g., integers, reals, strings).

Method calls are described in \[15.5\].

The use of \textit{this-intent} is described in \[15.5.1\].

\subsection{15.1.5 Nested Classes}

A class or record defined within another class is a nested class (or record).

Nested classes or records can refer to fields and methods in the outer class (or record) implicitly, or explicitly by means of an \textit{outer} reference.

A nested class (or record) can be referenced only within its immediately enclosing class (or record).

\section{15.2 Inheritance}

A \textit{derived} class can inherit from one or more other classes by listing those classes in the derived class declaration. When inheriting from multiple base classes, only one of the base classes may contain fields. The other classes can only define methods. Note that a class can still be derived from a class that contains fields which is itself derived from a class that contains fields.

These restrictions on inheritance induce a class hierarchy which has the form of a tree. A variable referring to an instance of class $C$ can be cast to any type that is an ancestor of $C$. Note that casts to more- and less-derived classes are both permitted.

\textit{Future.} A derived class may also incorporate any number of records by listing them in the derived class declaration. As with record inheritance, this has the effect of injecting the record’s fields and methods into the new class type. Record inheritance does not induce a well-defined class hierarchy. See \[16.2\] for details.

\subsection{15.2.1 The object Class}

All classes are derived from the \texttt{object} class, either directly or indirectly. If no class name appears in the inheritance list, the class derives implicitly from \texttt{object}. Otherwise, a class derives from \texttt{object} indirectly through the class or classes it inherits. A variable of type \texttt{object} can hold a reference to an object of any class type.

\subsection{15.2.2 Accessing Base Class Fields}

A derived class contains data associated with the fields in its base classes. The fields can be accessed in the same way that they are accessed in their base class unless the getter or setter method is overridden in the derived class, as discussed in \[15.2.5\].
15.2.3 Derived Class Constructors

The default initializer of a derived class automatically calls the default initializer of each of its base classes. The same is not true for constructors: To initialize inherited fields to anything other than its default-initialized value, a constructor defined in a derived class must either call base class constructors or manipulate those base-class fields directly.

*Open issue.* The syntax for calling a base-class constructor from a derived-class constructor has not yet been defined.

There is an expectation that a more standard way of chaining constructor calls will be supported.

15.2.4 Shadowing Base Class Fields

A field in the derived class can be declared with the same name as a field in the base class. Such a field shadows the field in the base class in that it is always referenced when it is accessed in the context of the derived class.

*Open issue.* There is an expectation that there will be a way to reference the field in the base class but this is not defined at this time.

15.2.5 Overriding Base Class Methods

If a method in a derived class is declared with a signature identical to that of a method in a base class, then it is said to override the base class’s method. Such a method is a candidate for dynamic dispatch in the event that a variable that has the base class type references an object that has the derived class type.

The identical signature requires that the names, types, and order of the formal arguments be identical. The return type of the overriding method must be the same as the return type of the base class’s method, or must be a subclass of the base class method’s return type.

Methods without parentheses are not candidates for dynamic dispatch.

*Rationale.* Methods without parentheses are primarily used for field accessors. A default is created if none is specified. The field accessor should not dispatch dynamically since that would make it impossible to access a base field within a base method should that field be shadowed by a subclass.

15.2.6 Inheriting from Multiple Classes

A class can be derived from multiple base classes provided that only one of the base classes contains fields either directly or from base classes that it is derived from. The methods defined by the other base classes can be overridden. This provides functionality similar to the C# concept of interfaces.

*Open issue.* It is an open question whether the language will support interface declarations and multiple inheritance. This is currently under study at the University of Colorado (Boulder).
15.2.7 The nil Value

Chapel provides nil to indicate the absence of a reference to any object. nil can be assigned to a variable of any class type. Invoking a class method or accessing a field of the nil value results in a run-time error.

\[ \text{nil-expression:} \]
\[ \text{nil} \]

15.2.8 Default Initialization

When an instance of a class (an object) is created, it is brought to a known and legal state first, before it can be accessed or operated upon. This is done through default initialization.

An object is default-initialized by initializing all of its fields in the order of the field declarations within the class. Fields inherited from a superclass are initialized before fields declared in current class.

If a field in the class is declared with an initialization expression, that expression is used to initialize the field. Otherwise, the field is initialized to the default value of its type (§8.1.1).

15.3 Class Constructors

Class instances are created by invoking class constructors. A class constructor is a method with the same name as the class. It is invoked by the new operator, where the class name and constructor arguments are preceded with the new keyword.

When the constructor is called, memory is allocated to store a class instance, the instance undergoes default initialization, and then the constructor method is invoked on this newly-created instance.

If the program declares a class constructor method, it is a user-defined constructor. If the program declares no constructors for a class, a compiler-generated constructor for that class is created automatically.

15.3.1 User-Defined Constructors

A user-defined constructor is a constructor method explicitly declared in the program. A constructor declaration has the same syntax as a method declaration, except that the name of the function matches the name of the class, and there is no return type specifier.

A constructor for a given class is called by placing the new operator in front of the class name. Any constructor arguments follow the class name in a parenthesized list.

\[ \text{constructor-call-expression:} \]
\[ \text{new class-name ( argument-list )} \]

\[ \text{class-name:} \]
\[ \text{identifier} \]
When a constructor is called, the usual function resolution mechanism (§13.12) is applied to determine which user-defined constructor to invoke.

**Example (simpleConstructors.chpl).** The following example shows a class with two constructors:

```chapel
class MessagePoint {
  var x, y: real;
  var message: string;

  proc MessagePoint(x: real, y: real) {
    this.x = x;
    this.y = y;
    this.message = "a point";
  }

  proc MessagePoint(message: string) {
    this.x = 0;
    this.y = 0;
    this.message = message;
  }
} // class MessagePoint

// create two objects
var mp1 = new MessagePoint(1.0,2.0);
var mp2 = new MessagePoint("point mp2");
```

The first constructor lets the user specify the initial coordinates and the second constructor lets the user specify the initial message when creating a MessagePoint.

Constructors for generic classes (§22.3) handle certain arguments differently and may need to satisfy additional requirements. See Section §22.3.7 for details.

### 15.3.2 The Compiler-Generated Constructor

A compiler-generated constructor for a class is created automatically if there are no constructors for that class in the program. The compiler-generated constructor has one argument for every field in the class, each of which has a default value equal to the field’s initializer (if present) or default value of the field’s type (if not). The list of fields (and hence arguments) includes fields inherited from superclasses, type aliases and parameter fields, if any. The order of the arguments in the argument list matches the order of the field declarations within the class, with the arguments for a superclass’s fields occurring before the arguments for the fields declared in current class.

Generic fields are treated separately which are discussed in Section §22.3.6.

When invoked, the compiler-generated constructor initializes each field in the class to the value of the corresponding actual argument.

**Example (defaultConstructor.chpl).** Given the class

```chapel
class C {
  var x: int;
  var y: real = 3.14;
  var z: string = "Hello, World!";
}
```
there are no user-defined constructors for \( C \), so \texttt{new} operators will invoke \( C \)'s compiler-generated constructor. The \( x \) argument of the compiler-generated constructor has the default value 0. The \( y \) and \( z \) arguments have the default values 3.14 and "Hello, World!", respectively.

\( C \) instances can be created by calling the compiler-generated constructor as follows:

- The call \texttt{new C()} is equivalent to \texttt{C(0,3.14,"Hello, World!")}.
- The call \texttt{new C(2)} is equivalent to \texttt{C(2,3.14,"Hello, World!")}.
- The call \texttt{new C(z="")} is equivalent to \texttt{C(0,3.14,"")}.
- The call \texttt{new C(2,z="")} is equivalent to \texttt{C(2,3.14,"")}.
- The call \texttt{new C(0,0.0,"")} specifies the initial values for all fields explicitly.

### 15.4 Field Accesses

The field in a class is accessed via a field access expression.

\[
\text{field-access-expression:} \\
\quad \text{receiver-clause\_opt identifier} \\
\]

\[
\text{receiver-clause:} \\
\quad \text{expression .} \\
\]

The receiver-clause specifies the \textit{receiver}, which is the class instance whose field is being accessed. The receiver clause can be omitted when the field access is within a method. In this case the receiver is the method's receiver \[\text{§15.5.1}\]. The receiver clause can also be omitted when the field access is within a class declaration. In this case the receiver is the instance being implicitly defined or referenced.

The identifier in the field access expression indicates which field is accessed.

A field can be modified via an assignment statement where the left-hand side of the assignment is a field access expression. Accessing a parameter field returns a parameter.

\textit{Example (useActor1.chpl).} Given a variable \texttt{anActor} of type \texttt{Actor} as defined above, the code

\[
\text{var s: string = anActor.name;
anActor.age = 27;
}
\]

reads the field \texttt{name} and assigns the value to the variable \texttt{s}, and assigns the field \texttt{age} in the object \texttt{anActor} the value 27.

### 15.4.1 Variable Getter Methods

All field accesses are performed via getters. A getter is a method without parentheses with the same name as the field. It is defined in the field's class and has a \texttt{ref} return intent (\[\text{§13.7.1}\]). If the program does not define it, the default getter, which simply returns the field, is provided.

\textit{Example (getterSetter.chpl).} In the code
class C {
    var setCount: int;
    var x: int;
    proc x ref {
        if setter then
            setCount += 1;
        return x;
    }
}

an explicit variable getter method is defined for field $x$. It returns the field $x$ and increments another field that records the number of times $x$ was assigned a value.

15.5 Class Method Calls

A method is invoked with a method call, which is similar to a non-method call expression.

\[
\text{method-call-expression:} \quad \text{receiver-clauseopt expression ( named-expression-list )} \\
\quad \text{receiver-clauseopt expression [ named-expression-list ]} \\
\quad \text{receiver-clauseopt parenthesesless-function-identifier}
\]

The receiver-clause (or its absence) specifies the method’s receiver [15.5.1] in the same way it does for field accesses [15.4].

Example (defineMethod.chpl). A method to output information about an instance of the `Actor` class can be defined as follows:

```chapel
proc Actor.print() {
    writeln("Actor ", name, " is ", age, " years old");
}
```

This method can be called on an instance of the `Actor` class, `anActor`, with the call expression `anActor.print()`.

The actual arguments supplied in the method call are bound to the formal arguments in the method declaration following the rules specified for procedures ([13]). The exception is the receiver [15.5.1].

15.5.1 The Method Receiver and the `this` Argument

A method’s `receiver` is an implicit formal argument named `this` representing the expression on which the method is invoked. The receiver’s actual argument is specified by the `receiver-clause` of a method-call-expression as specified in [15.4].

Example (implicitThis.chpl). Let class `C`, method `foo`, and function `bar` be defined as

```chapel
class C {
    proc foo() {
        bar(this);
    }
}
proc bar(c: C) { writeln(c); }
```
Then given an instance of \( C \) called \( c1 \), the method call \( c1.foo() \) results in a call to \( \text{bar} \) where the argument is \( c1 \). Within primary method \( C.foo() \), the (implicit) receiver formal has static type \( C \) and is referred to as \( \text{this} \).

Methods whose receivers are objects are called \textit{instance methods}. Methods may also be defined to have \textit{type} receivers—these are known as \textit{type methods}.

The optional \textit{this-intent} is used to specify type methods, to constrain a receiver argument to be a \texttt{param}, or to specify how the receiver argument should be passed to the method.

A method whose \textit{this-intent} is \texttt{type} defines a \textit{type method}. It can only be called on the type itself rather than on an instance of the type. When \textit{this-intent} is \texttt{param}, it specifies that the function can only be applied to \texttt{param} objects of the given type binding.

\textbf{Example (paramTypeThisIntent.chpl).} In the following code, the \texttt{isOdd} method is defined with a \textit{this-intent} of \texttt{param}, permitting it to be called on \texttt{params} only. The \texttt{size} method is defined with a \textit{this-intent} of \texttt{type}, requiring it to be called on the \texttt{int} type itself, not on integer values.

\begin{verbatim}
proc param int.isOdd(int) param
{
  return this & 0x1 == 0x1;
}

proc type int.size() param
{
  return 64;
}

param three = 3;
var seven = 7;

writeln(42.isOdd());       // prints false
writeln(three.isOdd());    // prints true
writeln((42+three).isOdd())); // prints true
// writeln(seven.isOdd());  // illegal since ‘seven’ is not a param

writeln(int.size());       // prints 64
// writeln(42.size());     // illegal since ‘size()’ is a static method
\end{verbatim}

When \textit{this-intent} is \texttt{ref}, the receiver argument will be passed by reference, allowing modifications to \texttt{this}. If no \textit{this-intent} is specified, the receiver will be passed with the default intent as specified in \ref{refThisIntent.chpl}.

\textbf{Example (refThisIntent.chpl).} In the following code, the \texttt{doubleMe} function is defined with a \textit{this-intent} of \texttt{ref}, allowing variables of type \texttt{int} to double themselves.

\begin{verbatim}
proc ref int.doubleMe() { this *= 2; }

Given a variable \( x = 2 \), a call to \( x.doubleMe() \) will set \( x \) to \( 4 \).
\end{verbatim}

\section{The this Method}

A procedure method declared with the name \texttt{this} allows a class to be “indexed” similarly to how an array is indexed. Indexing into a class instance has the semantics of calling a method named \texttt{this}. There is no other way to call a method called \texttt{this}. The \texttt{this} method must be declared with parentheses even if the argument list is empty.
Example (thisMethod.chpl). In the following code, the this method is used to create a class that acts like a simple array that contains three integers indexed by 1, 2, and 3.

```chapel
class ThreeArray {
    var x1, x2, x3: int;
    proc this(i: int) ref {
        select i {
            when 1 do return x1;
            when 2 do return x2;
            when 3 do return x3;
        }
        halt("ThreeArray index out of bounds: ", i);
    }
}
```

15.7 The these Method

An iterator method declared with the name these allows a class to be “iterated over” similarly to how a domain or array is iterated over. Using a class in the context of a loop where an iterable-expression is expected has the semantics of calling a method on the class named these.

Example (theseIterator.chpl). In the following code, the these method is used to create a class that acts like a simple array that can be iterated over and contains three integers.

```chapel
class ThreeArray {
    var x1, x2, x3: int;
    iter these() ref {
        yield x1;
        yield x2;
        yield x3;
    }
}
```

15.8 Common Operations

15.8.1 Class Assignment

Classes are assigned by reference. After an assignment from one variable of a class type to another, both variables reference the same class instance.

15.8.2 Implicit Class Conversions

An implicit conversion from class type D to another class type C is allowed when D is a subclass of C. The value nil can be implicitly converted to any class type. These conversions do not change the value.
15.9 Dynamic Memory Management

Memory associated with class instances can be reclaimed with the delete statement:

```
deadle-statement:
delele expression ;
```

where the expression is a reference to the instance that will be reclaimed. The expression may evaluate to nil, in which case the delete statement has no effect. If an object is referenced after it has been deleted, the behavior is undefined.

Example (delete.chpl). The following example allocates a new object \( c \) of class type \( C \) and then deletes it.

```
var c : C = nil;
delete c;  // Does nothing: c is nil.
c = new C();  // Creates a new object.
delete c;  // Deletes that object.
```

// The following statements reference an object after it has been deleted, so
// the behavior of each is "undefined":
// writeln(c.i);  // May read from freed memory.
// c.i = 3;  // May overwrite freed memory.
// delete c;  // May confuse some allocators.

Open issue. Chapel was originally specified without a delete keyword. The intention was that Chapel would be implemented with a distributed-memory garbage collector. This is a research challenge. In order to focus elsewhere, the design has been scaled back. There is an expectation that Chapel will eventually support an optional distributed-memory garbage collector as well as a region-based memory management scheme similar to that used in the Titanium language. Support of delete will likely continue even as these optional features become supported.

15.9.1 Class Destructor

A class author may specify additional actions to be performed before a class object is reclaimed, by defining a class destructor. A class destructor is a method that has the same name as the class prefixed by a tilde. A class destructor takes no arguments (aside from the implicit this argument). If defined, the destructor is called each time a delete statement is invoked with a valid instance of that class type. The destructor is not called if the argument of delete evaluates to nil.

Example (classDestructor.chpl).

```
class C {  
  var i,j,k: int;
  proc `C() { writeln("Bye, bye."); }  
}

var c : C = nil;
delete c;  // Does nothing: c is nil.
c = new C();  // Creates a new object.
delete c;  // Deletes that object: Writes out "Bye, bye."  
            // and reclaims the memory that was held by c.
```
16 Records

A record is a data structure that is similar to a class but instead has value semantics, similar to primitive types. Value semantics mean that assignment, argument passing and function return values are by default all done by copying. Value semantics also imply that a variable of record type is associated with only one piece of storage and has only one type throughout its lifetime. Storage is allocated for a variable of record type when the variable declaration is executed, and the record variable is also initialized at that time.

A record declaration creates a record type [16.1]. A variable of record type contains all and only the fields defined by that type ([16.1.1]). Value semantics imply that the type of a record variable is known at compile time (i.e. it is statically typed).

Records can be created through an explicit call to a record constructor, which allocates storage, initializes it and returns it. A record is also created upon a variable declaration of a record type.

A record type is generic if it contains generic fields. Generic record types are discussed in detail in [22.3].

16.1 Record Declarations

A record is defined with the following syntax:

```
record-declaration-statement:
  simple-record-declaration-statement
  external-record-declaration-statement

simple-record-declaration-statement:
  record identifier record-inherit-list opt { record-statement-list }

record-inherit-list:
  : record-type-list

record-type-list:
  record-type
  record-type , record-type-list

record-statement-list:
  record-statement
  record-statement record-statement-list

record-statement:
  variable-declaration-statement
  method-declaration-statement
  type-declaration-statement
  empty-statement
```

A `record-declaration-statement` defines a new type symbol specified by the identifier. A record inherits data and methods from other records if the `record-inherit-list` is specified.
Records

Future. Allowing a record to inherit from more than one record is future work.

Rationale. We do not allow records to inherit from classes because of the following.

Inheritance implies that the derived type can be cast to one of its base types. If the base type is a record type, casting to the base type has the effect of removing all of the data fields and all of functions that are not associated with the base type. Thereafter, the record variable has the base record type, in both compile-time and run-time interpretations.

If the base type were a class type, the result of the cast would have the static type of the base class while its run-time type was a record type. Since a record’s type is supposed to be determined at compile time, this is a bit incongruous with the definition of a record. Moreover, space would have to be allocated in this special case, to store the record’s run-time type.

As in a class declarations, the body of a record declaration can contain variable, iterator and method declarations as well as nested type declarations.

If a record declaration contains a type alias or parameter field, or it contains a variable or constant without a specified type and without an initialization expression, then it declares a generic record type. Generic record types are described in \[\text{§22.3}\].

If the \texttt{extern} keyword appears before the \texttt{record} keyword, then an external record type is declared. An external record type declaration must not contain a \texttt{record-inherit-list}. An external record is used within Chapel for type and field resolution, but no corresponding backend definition is generated. It is presumed that the definition of an external record is supplied by a library or the execution environment. See the chapter on interoperability (\[\text{§30}\]) for more information on external records.

Future. Privacy controls for classes and records are currently not specified, as discussion is needed regarding its impact on inheritance, for instance.

16.1.1 Record Types

A record type specifier simply names a record type, using the following syntax:

\begin{verbatim}
record-type:
  identifier
  identifier ( named-expression-list )
\end{verbatim}

A record type specifier may appear anywhere a type specifier is permitted.

For non-generic records, the record name by itself is sufficient to specify the type. Generic records must be instantiated to serve as a fully-specified type, for example to declare a variable. This is done with type constructors, which are defined in Section \[\text{22.3.4}\].
16.1.2 Record Fields

Variable declarations within a record type declaration define fields within that record type. The presence of at least one parameter field causes the record type to become generic. Variable fields define the storage associated with a record.

Example (defineActorRecord.chpl). The code

```chpl
record ActorRecord {
  var name: string;
  var age: uint;
}
```

defines a new record type called ActorRecord that has two fields: the string field name and the unsigned integer field age. The data contained by a record of this type is exactly the same as that contained by an instance of the Actor class defined in the preceding chapter §15.1.3.

16.1.3 Record Methods

A record method is a function or iterator that is bound to a record. Unlike functions that take a record as an argument, record methods access the record by reference, so that persistent field updates are possible.

The syntax for record method declarations is identical to that for class method declarations (§15.1.4).

16.1.4 Nested Record Types

Record type declarations may be nested within other class, record and union declarations. Methods defined in a nested record type may access fields declared in the containing aggregate type either implicitly, or explicitly by means of an outer reference.

16.2 Record Inheritance

A derived record type is a type that inherits from other record types. For each named base record type, inheritance effectively inserts all of its fields and methods into the new record type.

Since record types are resolved statically, there is no type hierarchy implied by record inheritance. It is merely a shorthand for including a list of fields in the record (or class) type being defined. Record inheritance can be useful for grouping data common to several or class or record types.

Future. From the definition of record inheritance, it is apparent that a record of a derived type can be cast legally to any of its base record types. But given their semantics, records can also be legally cast to types with which they have no inheritance relationship. Thus, records do not induce a well-defined type hierarchy.

Example (recordInheritance.chpl).
The record `Center` is defined and used as a shorthand in defining the `Circle` and `Ellipse` records. The `Circle` record contains three `real` fields named `x`, `y` and `radius`. The `Ellipse` record contains four `real` fields named `x`, `y`, `major` and `minor`.

The syntax and semantics for accessing methods (including getter methods and hence fields) in a base record type is the same as for accessing fields in a base class (§15.2.2).

### 16.2.1 Shadowing Base Record Fields

A field in the derived record can be declared with the same name as a field in a base record. Such a field shadows the field in the base record, meaning that the field by the same name in the base record is not directly accessible.

*Open issue.* A syntax for accessing shadowed fields has not yet been specified.

### 16.2.2 Overriding Base Record Methods

*Future.* If a method in a derived record is declared with a signature identical to that of a method in a base record, then it is said to override the base record’s method. Since records do not support dynamic dispatch, method overriding is the same as method shadowing: When referenced via the derived record type, the derived type’s version of the method is called; when referenced via the base record type, the base record type’s version of the method is called.

The identical signature requires that the names, types, and order of the formal arguments be identical. The return type of the overriding method must be the same as the return type of the base record’s method, or must be a subrecord of the base record method’s return type.

### 16.3 Record Variable Declarations

A record variable declaration is a variable declaration using a record type. When a variable of record type is declared, storage is allocated sufficient to store all of the fields defined in that record type.

In the context of a class or record or union declaration, the fields are allocated within the object as if they had been declared individually. In this sense, records provide a way to group related fields within a containing class or record type.

In the context of a function body, a record variable declaration causes storage to be allocated sufficient to store all of the fields in that record type. The record variable is initialized through a call to its default initializer. The default initializer for a record is defined in the same way as the default initializer for a class (§15.2.8).
16.3.1 Storage Allocation

Storage for a record variable directly contains the data associated with the fields in the record, in the same manner as variables of primitive types directly contain the primitive values. Record storage is reclaimed when the record variable goes out of scope. No additional storage for a record is allocated or reclaimed. Field data of one variable’s record is not shared with data of another variable’s record.

16.3.2 Record Initialization

A variable of a record type declared without an initialization expression is initialized through a call to the record’s default initializer, passing no arguments. The default initializer for a record is defined in the same way as the default initializer for a class (§15.2.8).

If the new record type is derived from other record types, the default initializer for each base record will be called in lexical order before default initializer for the record itself.

To construct a record as an expression, i.e. without binding it to a variable, the new operator is required. In this case, storage is allocated and reclaimed as for a record variable declaration (§16.3.1), except that the temporary record goes out of scope at the end of the enclosing expression.

To initialize a record variable with a non-default value, it can be assigned the value of a constructor call expression. The constructors for a record are defined in the same way as those for a class (§15.3).

Rationale. The new keyword disambiguates types from values. This is needed because of the close relationship between constructors and type specifiers for classes and records.

Example (recordCreation.chpl). The program

```chpl
record TimeStamp {
    var time: string = "1/1/1011";
}

var timestampDefault: TimeStamp;  // use the default for 'time'
var timestampCustom = new TimeStamp("2/2/2022");  // ... or a different one
writeln(timestampDefault);
writeln(timestampCustom);

var idCounter = 0;
record UniqueID {
    var id: int;
    proc UniqueID() { idCounter += 1; id = idCounter; }
}

writeln(new UniqueID());  // create and use a record value without a variable
writeln(new UniqueID());
```

produces the output

```
(time = 1/1/1011)
(time = 2/2/2022)
(id = 1)
(id = 2)
```
The variable `timestampDefault` is initialized with `TimeStamp`'s default initializer. The expression `new TimeSpan` creates a record that is assigned to `timestampCustom`. It effectively initializes `timestampCustom` via a call to the constructor with desired arguments. The records created with `new UniqueID()` are discarded after they are used.

As with classes, the user can provide his own constructors (§15.3.1). If any user-defined constructors are supplied, the default initializer cannot be called directly.

### 16.3.3 Record Destructor

A record author may specify additional actions to be performed before record storage is reclaimed by defining a record destructor. A record destructor is a method that has the same name as the record prefixed by a tilde. A record destructor takes no arguments (aside from the implicit `this` argument). If defined, the destructor is called on a record object after it goes out of scope and before its memory is reclaimed.

**Example (recordDestructor.chpl).**

```chapel
class C { var x: int; } // A class with nonzero size.
// If the class were empty, whether or not its memory was reclaimed // would not be observable.

// Defines a record implementing simple memory management.
record R { var c: C;
    proc R() { c = new C(0); }
    proc ~R() { delete c; c = nil; }
}

proc foo()
{
    var r: R; // Initialized using default constructor.
    writeln(r);
    // r will go out of scope here.
    // Its destructor will be called to free the C object it contains.
}

foo();
```

### 16.4 Record Arguments

When records are copied into or out of a function’s formal argument, the copy is performed consistently with the semantics described for record assignment (§16.9.1).

**Example (paramPassing.chpl).** The program

```chapel
record MyColor {
    var color: int;
}
proc printMyColor(in mc: MyColor) {
    writeln("my color is ", mc.color);
    mc.color = 6; // does not affect the caller’s record
```
Records

```plaintext
}]

var mc1: MyColor;    // 'color' defaults to 0
var mc2: MyColor = mc1; // mc1’s value is copied into mc2
mc1.color = 3;       // mc1’s value is modified
printMyColor(mc2);   // mc2 is not affected by assignment to mc1
printMyColor(mc2);   // ... or by assignment in printMyColor()

proc modifyMyColor(inout mc: MyColor, newcolor: int) {
    mc.color = newcolor;
}
modifyMyColor(mc2, 7); // mc2 is affected because of the 'inout' intent
printMyColor(mc2);

produces
my color is 0
my color is 0
my color is 7
```

The assignment to mc1.color affects only the record stored in mc1. The record in mc2 is not affected by the assignment to mc1 or by the assignment in printMyColor. mc2 is affected by the assignment in modifyMyColor because the intent inout is used.

### 16.5 Record Field Access

A record field is accessed the same way as a class field ([15.4]). When a field access is used as an rvalue, the value of that field is returned. When it is used as an lvalue, the value of the record field is updated.

Member access expressions that access parameter fields produce a parameter.

#### 16.5.1 Field Getter Methods

As in classes, field accesses are performed via getter methods ([15.4.1]). By default, these methods simply return a reference to the specified field (so they can be written as well as read). The user may redefine these as needed.

### 16.6 Record Method Calls

A record method may be invoked the same way as a class method ([15.5]). Unlike class methods, record methods are resolved at compile time.

#### 16.6.1 The Method Receiver and the this Argument

The receiver of a record method is similar to and is determined in the same way as the receiver of a class method ([15.5.1]). The type of the receiver is the record in which the method is defined. The receiver formal argument can be referred to within the method using the identifier this.

The difference from a class method is that the receiver actual argument, which must be a record value, is passed to the record method by reference, rather than by copying. Therefore updates to the receiver made in the method, if any, are visible outside the method.
16.7 The *this* Method

As with classes, records can be supplied with a *this* method. This method defines the behavior of the indexing operator `[]`.

16.8 The *these* Method

A *these* method can be defined for records as well as classes (§15.7). It provides an iterator which iterates over the contents of the record in a user-defined manner.

16.9 Common Operations

16.9.1 Record Assignment

A variable of record type may be updated by assignment. The compiler provides a default assignment operator for each record type $R$ having the signature

```
Example.

proc = (ref lhs:R, rhs:R) : void ;
```

In it, the value of each field of the record on the right-hand side is assigned to the corresponding field of the record on the left-hand side.

The compiler-provided assignment operator may be overridden.

The following example demonstrates record assignment.

```
Example (assignment.chpl).

record R {
  var i: int;
  var x: real;
  proc print() { writeln("i = ", this.i, ", x = ", this.x); }
}

var A: R;
A.i = 3;
A.print(); // "i = 3, x = 0.0"

var C: R;
A = C;
A.print(); // "i = 0, x = 0.0"

C.x = 3.14;
A.print(); // "i = 0, x = 0.0"
```
Prior to the first call to `R.print`, the record `A` is created and initialized to all zeroes. Then, its `i` field is set to 3. For the second call to `R.print`, the record `C` is created assigned to `A`. Since `C` is default-initialized to all zeroes, those zero values overwrite both values in `A`.

The next clause demonstrates that `A` and `C` are distinct entities, rather than two references to the same object. Assigning `3.14` to `C.x` does not affect the `x` field in `A`.

*Open issue.* Whether reference assignment is to be supported is an open question. If so, it would work like reference assignment in C++ – basically creating an alias for the RHS. References can be used to reduce the length of dereference expression, and also improve performance – especially if that expression is used repeatedly.

16.9.2 Default Comparison Operators

Default functions to overload `==` and `!=` are defined for records if none are explicitly defined. The default implementation of `==` applies `==` to each field of the two argument records and reduces the result with the `&&` operator. The default implementation of `!=` applies `!=` to each field of the two argument records and reduces the result with the `||` operator.

16.9.3 Implicit Record Conversions

An expression of record type `D` can be implicitly converted to another record type `C` if

- for each field in `C` there is a like-named field in `D`, and
- an implicit conversion is allowed from the type of the field in `D` to the type of the field in `C`.

Such a conversion removes any fields that are in `D` but not `C`.

The value produced by such a conversion is a record of type `C`. The value of each field of this record is obtained by an implicit conversion of the corresponding field in `D` to that field’s type in `C`.

16.10 Differences between Classes and Records

The key differences between records and classes are listed below.

16.10.1 Declarations

Syntactically, class and record type declarations are identical, except that they begin with the `class` and `record` keywords, respectively. Also, a record type can only inherit from other record types. Class inheritance is not permitted.
16.10.2 Storage Allocation

For a variable of record type, storage necessary to contain the data fields has a lifetime equivalent to the scope in which it is declared. No two record variables share the same data. It is not necessary to call new to create a record.

By contrast, a class variable contains only a reference to a class instance. A class instance is created through a call to its new operator. Storage for a class instance, including storage for the data associated with the fields in the class, is allocated and reclaimed separately from variables referencing that instance. The same class instance can be referenced by multiple class variables.

16.10.3 Assignment

Assignment to a class variable is performed by reference, whereas assignment to a record is performed by value. When a variable of class type is assigned to another variable of class type, they both become names for the same object. In contrast, when a record variable is assigned to another record variable, then contents of the source record are copied into the target record field-by-field.

When a variable of class type is assigned to a record, matching fields (matched by name) are copied from the class instance into the corresponding record fields. Subsequent changes to the fields in the target record have no effect upon the class instance.

Assignment of a record to a class variable is not permitted.

16.10.4 Arguments

The semantics of argument passing is determined by the type of the formal argument (as declared inside the function header). An actual argument is of a type compatible with the formal argument only if it is legal to assign the actual to the formal.

Specifically, if the formal argument is of class type, the actual argument must be of that class type or of a type derived from that class type. If the formal argument is of a record type, then it is only necessary for the fields in the actual argument to “cover” the fields in the formal argument type.

The receiver argument is passed by value for class methods but is passed by reference for record methods. In both cases modifications to the receiver fields are visible outside the method.

16.10.5 Inheritance

The difference between record inheritance and class inheritance is that for records there is no dynamic dispatch. The record type of a variable is the exact type of that variable, i.e. a variable of a base record type cannot store a derived record type.

Casting a derived record type to a base record type truncates all fields except those belonging to the base record type. In the same way, only those methods accessible to the base record type may be invoked using the result of such a cast.
16.10.6 Shadowing and Overriding

Class variables have run-time types and (therefore) support dynamic dispatch. Records are statically typed, so they do not have run-time types and they do not support dynamic dispatch.

As a result, in record type hierarchies, shadowing and overriding are the same. Which field is accessed and/or which method is invoked is determined statically by the declared type of the record being referenced.

16.10.7 No nil Value

Records do not provide a counterpart of the nil value. A variable of record type is associated with storage throughout its lifetime, so nil has no meaning with respect to records.

16.10.8 The delete operator

Calling delete on a record is illegal.

16.10.9 Default Comparison Operators

For records, the compiler will supply default comparison operators if they are not supplied by the user. The compiler does not supply default comparison operators for classes.
17 Unions

Unions have the semantics of records, however, only one field in the union can contain data at any particular point in the program’s execution. Unions are safe so that an access to a field that does not contain data is a runtime error. When a union is constructed, it is in an unset state so that no field contains data.

17.1 Union Types

The syntax of a union type is summarized as follows:

\[
\text{union-type:} \\
\text{identifier}
\]

The union type is specified by the name of the union type. This simplification from class and record types is possible because generic unions are not supported.

17.2 Union Declarations

A union is defined with the following syntax:

\[
\text{union-declaration-statement:} \\
\text{extern-opt union identifier \{ union-statement-list \}}
\]

\[
\text{union-statement-list:} \\
\text{union-statement} \\
\text{union-statement union-statement-list}
\]

\[
\text{union-statement:} \\
\text{type-declaration-statement} \\
\text{procedure-declaration-statement} \\
\text{iterator-declaration-statement} \\
\text{variable-declaration-statement} \\
\text{empty-statement}
\]

If the `extern` keyword appears before the `union` keyword, then an external union type is declared. An external union is used within Chapel for type and field resolution, but no corresponding backend definition is generated. It is presumed that the definition of an external union type is supplied by a library or the execution environment.

17.2.1 Union Fields

Union fields are accessed in the same way that record fields are accessed. It is a runtime error to access a field that is not currently set.

Union fields should not be specified with initialization expressions.
17.3 Union Assignment

Union assignment is by value. The field set by the union on the right-hand side of the assignment is assigned to the union on the left-hand side of the assignment and this same field is marked as set.
18 Ranges

A range is a first-class, constant-space representation of a regular sequence of integer indices. Ranges support iteration over the sequences they represent and are the basis for defining domains (§19).

Ranges are presented as follows:

- definition of the key range concepts §18.1
- range types §18.2
- range values §18.3
- range assignment §18.4.1
- operators on ranges §18.5
- predefined functions on ranges §18.6

18.1 Range Concepts

A range has four primary properties. Together they define the sequence of indices that the range represents, or the represented sequence, as follows.

- The low bound is either an integer or $-\infty$.
- The high bound is either an integer or $+\infty$. The low and high bounds determine the span of the represented sequence. Chapel does not represent $\infty$ explicitly. Instead, infinite bound(s) are represented implicitly in the range’s type (§18.2). When the low and/or high bound is $\infty$, the represented sequence is unbounded in the corresponding direction(s).
- The stride is a non-zero integer. It defines the distance between any two adjacent members of the represented sequence. The sign of the stride indicates the direction of the sequence:
  - $\text{stride} > 0$ indicates an increasing sequence,
  - $\text{stride} < 0$ indicates a decreasing sequence.
- The alignment is either an integer or is ambiguous. It defines how the represented sequence’s members are aligned relative to 0. For a range with a stride other than 1 or -1, ambiguous alignment means that the represented sequence is undefined. In such a case, certain operations discussed later result in an error.
  
  Open issue. We consider disallowing ambiguous alignment for ranges whose both bounds are integers (not $\infty$), in order to enable more efficient implementation.
More formally, the represented sequence for the range \((\text{low}, \text{high}, \text{stride}, \text{alignment})\) contains all indices \(ix\) such that:

- \(\text{low} \leq ix \leq \text{high and } ix \equiv \text{alignment} \pmod{\text{stride}}\) if \(\text{alignment}\) is not ambiguous,
- \(\text{low} \leq ix \leq \text{high}\) if \(\text{stride} = 1\) or \(\text{stride} = -1\),
- the represented sequence is undefined otherwise.

The sequence, if defined, is increasing if \(\text{stride} > 0\) and decreasing if \(\text{stride} < 0\).

If the represented sequence is defined but there are no indices satisfying the applicable equation(s) above, the range and its represented sequence are empty.

We will say that an integer \(ix\) is aligned w.r.t. the range \((\text{low}, \text{high}, \text{stride}, \text{alignment})\) if:

- \(\text{alignment}\) is not ambiguous and \(ix \equiv \text{alignment} \pmod{\text{stride}}\), or
- \(\text{stride}\) is 1 or -1.

Furthermore, \(\infty\) is never aligned.

Ranges have the following additional properties.

- A range is ambiguously aligned if
  - its alignment is ambiguous, and
  - its stride is neither 1 nor -1.
- The first index is the first member of the represented sequence.
  A range has no first index when the first member is undefined, that is, in the following cases:
  - the range is ambiguously aligned,
  - the represented sequence is empty,
  - the represented sequence is increasing and the low bound is \(-\infty\),
  - the represented sequence is decreasing and the high bound is \(+\infty\).
- The last index is the last member of the represented sequence.
  A range has no last index when the last member is undefined, that is, in the following cases:
  - it is ambiguously aligned,
  - the represented sequence is empty,
  - the represented sequence is increasing and the high bound is \(+\infty\),
  - the represented sequence is decreasing and the low bound is \(-\infty\).
- The aligned low bound is the smallest integer that is greater than or equal to the low bound and is aligned w.r.t. the range, if such an integer exists.
  The aligned low bound equals the smallest member of the represented sequence, when both exist.
- The aligned high bound is the largest integer that is less than or equal to the high bound and is aligned w.r.t. the range, if such an integer exists.
  The aligned high bound equals the largest member of the represented sequence, when both exist.
- The range is iterable, that is, it is legal to iterate over it, if is has the first index.
18.2 Range Types

The type of a range is characterized by three parameters:

- **idxType** is the type of the indices of the range’s represented sequence. However, when the range’s low and/or high bound is $\infty$, the represented sequence also contains indices that are not representable by idxType. idxType must be an integral type and is int by default. The range’s low bound and high bound (when they are not $\infty$) and alignment are of the type idxType. The range’s stride is of the signed integer type that has the same bit size as idxType.

- **boundedType** indicates which of the range’s bounds are not $\infty$. boundedType is an enumeration constant of the type BoundedRangeType. It is discussed further below.

- **stridable** is a boolean that determines whether the range’s stride can take on values other than 1. stridable is false by default. A range is called stridable if its type’s stridable is true.

boundedType is one of the constants of the following type:

```
enum BoundedRangeType { bounded, boundedLow, boundedHigh, boundedNone };
```

The value of boundedType determines which bounds of the range are integers (making the range “bounded”, as opposed to infinite, in the corresponding direction(s)) as follows:

- **bounded**: both bounds are integers.
- **boundedLow**: the low bound is an integer (the high bound is $+\infty$).
- **boundedHigh**: the high bound is an integer (the low bound is $-\infty$).
- **boundedNone**: neither bound is an integer (both bounds are $\infty$).

boundedType is BoundedRangeType.bounded by default.

The parameters idxType, boundedType and stridable affect all values of the corresponding range type. For example, the range’s low bound is $-\infty$ if and only if the boundedType of that range’s type is either boundedHigh or boundedNone.

Rationale. Providing boundedType and stridable in a range’s type allows the compiler to identify the more common cases where the range is bounded and/or its stride is 1. The compiler can also detect user and library code that is specialized to these cases. As a result, the compiler has the opportunity to optimize these cases and the specialized code more aggressively.

A range type has the following syntax:

```
range-type:
  range ( named-expression-list )
```

That is, a range type is obtained as if by invoking the range type constructor ([22.3.4](#)) that has the following header:
Ranges

```
proc range(type idxType = int,
param boundedType = BoundedRangeType.bounded,
param stridable = false) type
```

As a special case, the keyword `range` without a parenthesized argument list refers to the range type with the default values of all its parameters, i.e., `range(int, BoundedRangeType.bounded, false)`.

*Example (rangeVariable.chpl).* The following declaration declares a variable `r` that can represent ranges of 32-bit integers, with both high and low bounds specified, and the ability to have a stride other than 1.

```chapel
var r: range(int(32), BoundedRangeType.bounded, stridable=true);
```

### 18.3 Range Values

A range value consists of the range’s four primary properties ([§18.1](#)): low bound, high bound, stride and alignment.

#### 18.3.1 Range Literals

Range literals are specified with the following syntax.

```
range-literal:
  expression .. expression
  expression ..
  .. expression
```

The expressions to the left and to the right of `..`, when given, are called the low bound and the high bound expression, respectively.

The type of a range literal is a range with the following parameters:

- **idxType** is determined as follows:
  - If both the low bound and the high bound expressions are given and have the same integral type, then `idxType` is that type.
  - If both the low bound and the high bound expressions are given and an implicit conversion is allowed from each expression’s type to the same integral type, then `idxType` is that integral type.
  - If only one bound expression is given and it has an integral type or an implicit conversion is allowed from that expression’s type to an integral type, then `idxType` is that integral type.
  - If neither bound expression is given, then `idxType` is `int`.
  - Otherwise, the range literal is not legal.

- **boundedType** is a value of the type `BoundedRangeType` that is determined as follows:
  - `bounded`, if both the low bound and the high bound expressions are given,
  - `boundedLow`, if only the high bound expression is given,
Ranges

- `boundedHigh`, if only the low bound expression is given,
- `boundedNone`, if neither bound expression is given.

- `stridable` is `false`.

The value of a range literal is as follows:

- The low bound is given by the low bound expression, if present, and is \(-\infty\) otherwise.
- The high bound is given by the upper bound expression, if present, and is \(+\infty\) otherwise.
- The stride is 1.
- The alignment is ambiguous.

18.3.2 Default Values

The default value for a range type depends on the type’s `boundedType` parameter as follows:

- `1..0` (an empty range) if `boundedType` is `bounded`
- `1..` if `boundedType` is `boundedLow`
- `..0` if `boundedType` is `boundedHigh`
- `..` if `boundedType` is `boundedNone`

*Rationale.* We use 0 and 1 to represent an empty range because these values are available for any `idxType`.

We have not found the natural choice of the default value for `boundedLow` and `boundedHigh` ranges. The values indicated above are distinguished by the following property. Slicing the default value for a `boundedLow` range with the default value for a `boundedHigh` range (or visa versa) produces an empty range, matching the default value for a `bounded` range.

18.4 Common Operations

All operations on a range return a new range rather than modifying the existing one. This supports a coding style in which all ranges are *immutable* (i.e. declared as `const`).

*Rationale.*

The intention is to provide ranges as immutable objects.

Immutable objects may be cached without creating coherence concerns. They are also inherently thread-safe. In terms of implementation, immutable objects are created in a consistent state and stay that way: Outside of constructors, internal consistency checks can be dispensed with.

These are the same arguments as were used to justify making strings immutable in Java and C#.
18.4.1 Range Assignment

Assigning one range to another results in the target range copying the low and high bounds, stride, and alignment from the source range.

Range assignment is legal when:

- An implicit conversion is allowed from idxType of the source range to idxType of the destination range type,
- the two range types have the same boundedType, and
- either the destination range is stridable or the source range’s stride is 1.

18.4.2 Range Comparisons

Ranges can be compared using equality and inequality.

```chapel
proc ==(r1: range(?), r2: range(?)): bool
```

Returns true if the two ranges have the same represented sequence or the same four primary properties, and false otherwise.

18.4.3 Iterating over Ranges

A range can be used as an iterator expression in a loop. This is legal only if the range is iterable. In this case the loop iterates over the members of the range’s represented sequence, in the order defined by the sequence. If the range is empty, no iterations are executed.

*Cray’s Chapel Implementation.* An attempt to iterate over a range causes an error if adding stride to the range’s last index overflows its index type, i.e. if the sum is greater than the index type’s maximum value, or smaller than its minimum value.

Iterating over Unbounded Ranges in Zippered Iterations

When a range with the first index but without the last index is used in a zippered iteration (§11.9.1), it generates as many indices as needed to match the other iterator(s).

*Example (zipWithUnbounded.chpl).* The code

```chapel
for i in zip(1..5, 3..) do
  write(i, "; ");
```

produces the output

```
(1, 3); (2, 4); (3, 5); (4, 6); (5, 7);
```
18.5 Range Operators

The following operators can be applied to range expressions and are described in this section: stride (by), alignment (align), count (count) and slicing (slice) or (sliced). Chapel also defines a set of functions that operate on ranges. They are described in §18.6.

\[
\text{range-expression:} \\
\text{expression} \\
\text{strided-range-expression} \\
\text{counted-range-expression} \\
\text{aligned-range-expression} \\
\text{sliced-range-expression}
\]

18.5.1 By Operator

The by operator selects a subsequence of the range’s represented sequence, optionally reversing its direction. The operator takes two arguments, a base range and an integral step. It produces a new range whose represented sequence contains each \( \text{step} \)-th element of the base range’s represented sequence. The operator reverses the direction of the represented sequence if \( \text{step} < 0 \). If the resulting sequence is increasing, it starts at the base range’s aligned low bound, if it exists. If the resulting sequence is decreasing, it starts at the base range’s aligned high bound, if it exists. Otherwise, the base range’s alignment is used to determine which members of the represented sequence to retain. If the base range’s represented sequence is undefined, the resulting sequence is undefined, too.

The syntax of the by operator is:

\[
\text{strided-range-expression:} \\
\text{range-expression by step-expression}
\]

\[
\text{step-expression:} \\
\text{expression}
\]

The type of the step must be a signed or unsigned integer of the same bit size as the base range’s idxType, or an implicit conversion must be allowed to that type from the step’s type. It is an error for the step to be zero.

\text{Future.} \quad \text{We may consider allowing the step to be of any integer type, for maximum flexibility.}

The type of the result of the by operator is the type of the base range, but with the stridable parameter set to true.

Formally, the result of the by operator is a range with the following primary properties:

- The low and upper bounds are the same as those of the base range.
- The stride is the product of the base range’s stride and the step, cast to the base range’s stride type before multiplying.
- The alignment is:
  - the aligned low bound of the base range, if such exists and the stride is positive;
- the aligned high bound of the base range, if such exists and the stride is negative;
- the same as that of the base range, otherwise.

**Example (rangeByOperator.chpl).** In the following declarations, range \( r_1 \) represents the odd integers between 1 and 20. Range \( r_2 \) strides \( r_1 \) by two and represents every other odd integer between 1 and 20: 1, 5, 9, 13 and 17.

```chapel
var r1 = 1..20 by 2;
var r2 = r1 by 2;
```

**Rationale.** *Why isn’t the high bound specified first if the stride is negative?* The reason for this choice is that the \( \text{by} \) operator is binary, not ternary. Given a range \( R \) initialized to \( 1..3 \), we want \( R \) by \(-1\) to contain the ordered sequence 3, 2, 1. But then \( R \) by \(-1\) would be different from \( 3..1 \) by \(-1\) even though it should be identical by substituting the value in \( R \) into the expression.

### 18.5.2 Align Operator

The \( \text{align} \) operator can be applied to any range, and creates a new range with the given alignment.

The syntax for the \( \text{align} \) operator is:

\[
\text{aligned-range-expression}:
\text{range-expression align expression}
\]

The type of the resulting range expression is the same as that of the range appearing as the left operand. An implicit conversion from the type of the right operand to the index type of the operand range must be allowed. The resulting range has the same low and high bounds and stride as the source range. The alignment equals the \( \text{align} \) operator’s right operand and therefore is not ambiguous.

**Example (alignedStride.chpl).**

```chapel
var r1 = 0 .. 10 by 3 align 0;
for i in r1 do
    write(" ", i);
writeln(); // Produces "0 3 6 9".

var r2 = 0 .. 10 by 3 align 1;
for i in r2 do
    write(" ", i);
writeln(); // Produces "1 4 7 10".
```

When the stride is negative, the same indices are printed in reverse:

**Example (alignedNegStride.chpl).**
Ranges

```pascal
var r3 = 0 .. 10 by -3 align 0;
for i in r3 do
  write(" ", i);  // Produces "9 6 3 0".
writeln();

var r4 = 0 .. 10 by -3 align 1;
for i in r4 do
  write(" ", i);  // Produces "10 7 4 1".
writeln();
```

To create a range aligned relative to its first index, use the offset method (§18.6.4).

### 18.5.3 Count Operator

The `#` operator takes a range and an integral count and creates a new range containing the specified number of indices. The low or high bound of the left operand is preserved, and the other bound adjusted to provide the specified number of indices. If the count is positive, indices are taken from the start of the range; if the count is negative, indices are taken from the end of the range. The count must be less than or equal to the length of the range.

\[
\text{counted-range-expression:} \\
\text{range-expression} \ # \ \text{expression}
\]

The type of the count expression must be a signed or unsigned integer of the same bit size as the base range's `idxType`, or an implicit conversion must be allowed to that type from the count's type.

The type of the result of the `#` operator is the type of the range argument.

Depending on the sign of the count and the stride, the high or low bound is unchanged and the other bound is adjusted so that it is \( c \times \text{stride} - 1 \) units away. Specifically:

- If the count times the stride is positive, the low bound is preserved and the high bound is adjusted to be one less than the low bound plus that product.
- If the count times the stride is negative, the high bound is preserved and the low bound is adjusted to be one greater than the high bound plus that product.

**Rationale.** Following the principle of preserving as much information from the original range as possible, we must still choose the other bound so that exactly \( count \) indices lie within the range. Making the two bounds lie \( count \times \text{stride} - 1 \) apart will achieve this, regardless of the current alignment of the range.

This choice also has the nice symmetry that the alignment can be adjusted without knowing the bounds of the original range, and the same number of indices will be produced:

```pascal
r # 4 align 0  // Contains four indices.
r # 4 align 1  // Contains four indices.
r # 4 align 2  // Contains four indices.
r # 4 align 3  // Contains four indices.
```

It is an error to apply the count operator with a positive count to a range that has no first index. It is also an error to apply the count operator with a negative count to a range that has no last index. It is an error to apply the count operator to a range that is ambiguously aligned.
Example (rangeCountOperator.chpl). The following declarations result in equivalent ranges.

```
var r1 = 1..10 by -2 # -3;
var r2 = ..6 by -2 # 3;
var r3 = -6..6 by -2 # 3;
var r4 = 1..#6 by -2;
```

Each of these ranges represents the ordered set of three indices: 6, 4, 2.

18.5.4 Arithmetic Operators

The following arithmetic operators are defined on ranges and integral types:

```chisel
proc +(r: range, s: integral): range
proc +(s: integral, r: range): range
proc -(r: range, s: integral): range
```

The + and - operators apply the scalar via the operator to the range’s low and high bounds, producing a shifted version of the range. If the operand range is unbounded above or below, the missing bounds are ignored. The index type of the resulting range is the type of the value that would result from an addition between the scalar value and a value with the range’s index type. The bounded and stridable parameters for the result range are the same as for the input range.

The stride of the resulting range is the same as the stride of the original. The alignment of the resulting range is shifted by the same amount as the high and low bounds. It is permissible to apply the shift operators to a range that is ambiguously aligned. In that case, the resulting range is also ambiguously aligned.

Example (rangeAdd.chpl). The following code creates a bounded, non-stridable range \( r \) which has an index type of \( \text{int} \) representing the indices 0, 1, 2, 3. It then uses the + operator to create a second range \( r2 \) representing the indices 1, 2, 3, 4. The \( r2 \) range is bounded, non-stridable, and is represented by indices of type \( \text{int} \).

```
var r = 0..3;
var r2 = r + 1;  // 1..4
```

18.5.5 Range Slicing

Ranges can be sliced using other ranges to create new sub-ranges. The resulting range represents the intersection between the two ranges' represented sequences. The stride and alignment of the resulting range are adjusted as needed to make this true. idxType and the sign of the stride of the result are determined by the first operand.

Range slicing is specified by the syntax:

```
sliced-range-expression:
  range-expression ( range-expression )
  range-expression [ range-expression ]
```

If either of the operand ranges is ambiguously aligned, then the resulting range is also ambiguously aligned. In this case, the result is valid only if the strides of the operand ranges are relatively prime. Otherwise, an error is generated at run time.
Ranges

**Rationale.** If the strides of the two operand ranges are relatively prime, then they are guaranteed to have some elements in their intersection, regardless whether their relative alignment can be determined. In that case, the bounds and stride in the resulting range are valid with respect to the given inputs. The alignment can be supplied later to create a valid range.

If the strides are not relatively prime, then the result of the slicing operation would be completely ambiguous. The only reasonable action for the implementation is to generate an error.

If the resulting represented sequence cannot be expressed as a range of the expected type, an error is generated. This can happen, for example, when the operands represent all odd and all even numbers, or when the first operand is an unbounded range with unsigned `idxType` and the second operand represents only negative numbers.

**Example (rangeSlicing.chpl).** In the following example, `r` represents the integers from 1 to 20 inclusive. Ranges `r2` and `r3` are defined using range slices and represent the indices from 3 to 20 and the odd integers between 1 and 20 respectively. Range `r4` represents the odd integers between 1 and 20 that are also divisible by 3.

```chapl
var r = 1..20;
var r2 = r[3..];
var r3 = r[1.. by 2];
var r4 = r3[0.. by 3];
```

### 18.6 Predefined Functions on Ranges

#### 18.6.1 Range Type Parameters

**proc range.boundedType : BoundedRangeType**

Returns the `boundedType` parameter of the range’s type.

**proc range.idxType : type**

Returns the `idxType` parameter of the range’s type.

**proc range.stridable : bool**

Returns the `stridable` parameter of the range’s type.

#### 18.6.2 Range Properties

Most of the methods in this subsection report on the range properties defined in §18.1. A range’s represented sequence can be examined, for example, by iterating over the range in a for loop §11.9.

**Open issue.** The behavior of the methods that report properties that may be undefined, `∞`, or ambiguous, may change.

**proc range.aligned : bool**
Ranges

Reports whether the range’s alignment is not ambiguous.

**proc range.alignedHigh : idxType**

Returns the range’s aligned high bound. If the aligned high bound is undefined (does not exist), the behavior is undefined.

*Example (alignedHigh.chpl)*. The following code:

```chpl
var r = 0..20 by 3;
writeln(r.alignedHigh);
```

produces the output

```
18
```

**proc range.alignedLow : idxType**

Returns the range’s aligned low bound. If the aligned low bound is undefined (does not exist), the behavior is undefined.

**proc range.alignment : idxType**

Returns the range’s alignment. If the alignment is ambiguous, the behavior is undefined. See also `aligned`.

**proc range.first : idxType**

Returns the range’s first index. If the range has no first index, the behavior is undefined. See also `hasFirst`.

**proc range.hasFirst() : bool**

Reports whether the range has the first index.

**proc range.hasHighBound() param: bool**

Reports whether the range’s high bound is not $+\infty$.

**proc range.hasLast() : bool**

Reports whether the range has the last index.

**proc range.hasLowBound() param: bool**

Reports whether the range’s low bound is not $-\infty$.

**proc range.high : idxType**

Returns the range’s high bound. If the high bound is $+\infty$, the behavior is undefined. See also `hasHighBound`.

**proc range.isAmbiguous() : bool**

Reports whether the range is ambiguously aligned.

**proc range.last : idxType**
Ranges

Returns the range’s last index. If the range has no last index, the behavior is undefined. See also hasLast.

proc range.length : idxType

Returns the number of indices in the range’s represented sequence. If the represented sequence is infinite or is undefined, an error is generated.

proc range.low : idxType

Returns the range’s low bound. If the low bound is -\(\infty\), the behavior is undefined. See also hasLowBound.

proc range.size : idxType

Same as range.length.

proc range.stride : int(numBits(idxType))

Returns the range’s stride. This will never return 0. If the range is not stridable, this will always return 1.

18.6.3 Other Queries

proc range.boundsCheck(r2: range(?)) : bool

Returns false if either range is ambiguously aligned. Returns true if range \(r2\) lies entirely within this range and false otherwise.

proc ident(r1: range(?), r2: range(?)) : bool

Returns true if the two ranges are the same in every respect: i.e. the two ranges have the same idxType, boundedType, stridable, low, high, stride and alignment values.

proc range.indexOrder(i: idxType) : idxType

If \(i\) is a member of the range’s represented sequence, returns an integer giving the ordinal index of \(i\) within the sequence using 0-based indexing. Otherwise, returns \((-1):\text{idxType}\). It is an error to invoke indexOrder if the represented sequence is not defined or the range does not have the first index.

Example. The following calls show the order of index 4 in each of the given ranges:

\[
\begin{align*}
(0..10).\text{indexOrder}(4) & \equiv 4 \\
(1..10).\text{indexOrder}(4) & \equiv 3 \\
(3..5).\text{indexOrder}(4) & \equiv 1 \\
(0..10 \text{ by } 2).\text{indexOrder}(4) & \equiv 2 \\
(3..5 \text{ by } 2).\text{indexOrder}(4) & \equiv -1
\end{align*}
\]

proc range.member(i: idxType) : bool

Returns true if the range’s represented sequence contains \(i\), false otherwise. It is an error to invoke member if the represented sequence is not defined.

proc range.member(other: range) : bool

Reports whether \(other\) is a subrange of the receiver. That is, if the represented sequences of the receiver and \(other\) are defined and the receiver’s sequence contains all members of the \(other\)’s sequence.
18.6.4 Range Transformations

proc range.alignHigh()

Sets the high bound of this range to its aligned high bound, if it is defined. Generates an error otherwise.

proc range.alignLow()

Sets the low bound of this range to its aligned low bound, if it is defined. Generates an error otherwise.

proc range.expand(i: idxType)

Returns a new range whose bounds are extended by $i$ units on each end. If $i < 0$ then the resulting range is contracted by its absolute value. In symbols, given that the operand range is represented by the tuple $(l, h, s, a)$, the result is $(l - i, h + i, s, a)$. The stride and alignment of the original range are preserved. If the operand range is ambiguously aligned, then so is the resulting range.

proc range.exterior(i: idxType)

Returns a new range containing the indices just outside the low or high bound of the range (low if $i < 0$ and high otherwise). The stride and alignment of the original range are preserved. Let the operand range be denoted by the tuple $(l, h, s, a)$. Then:

- if $i < 0$, the result is $(l + i, l - 1, s, a)$,
- if $i > 0$, the result is $(h + 1, h + i, s, a)$, and
- if $i = 0$, the result is $(l, h, s, a)$.

If the operand range is ambiguously aligned, then so is the resulting range.

proc range.interior(i: idxType)

Returns a new range containing the indices just inside the low or high bound of the range (low if $i < 0$ and high otherwise). The stride and alignment of the original range are preserved. Let the operand range be denoted by the tuple $(l, h, s, a)$. Then:

- if $i < 0$, the result is $(l, l - (i - 1), s, a)$,
- if $i > 0$, the result is $(h - (i - 1), h, s, a)$, and
- if $i = 0$, the result is $(l, h, s, a)$.

This differs from the behavior of the count operator, in that `interior()` preserves the alignment, and it uses the low and high bounds rather than `first` and `last` to establish the bounds of the resulting range. If the operand range is ambiguously aligned, then so is the resulting range.

proc range.offset(n: idxType)

Returns a new range whose alignment is this range’s first index plus $n$. The new alignment, therefore, is not ambiguous. If the range has no first index, a run-time error is generated.

proc range.translate(i: integral)

Returns a new range with its low, high and alignment values adjusted by $i$. The stride value is preserved. If the range’s alignment is ambiguous, the behavior is undefined.
19 Domains

A domain is a first-class representation of an index set. Domains are used to specify iteration spaces, to define the size and shape of arrays (§20), and to specify aggregate operations like slicing. A domain can specify a single- or multi-dimensional rectangular iteration space or represent a set of indices of a given type. Domains can also represent a subset of another domain’s index set, using either a dense or sparse representation. A domain’s indices may potentially be distributed across multiple locales as described in §27 thus supporting global-view data structures.

In the next subsection, we introduce the key characteristics of domains. In §19.2 we discuss the types and values that can be associated with a base domain. In §19.3 we discuss the types and values of simple subdomains that can be created from those base domains. In §19.4 we discuss the types and values of sparse subdomains. The remaining sections describe the important manipulations that can be performed with domains, as well as the predefined operators and functions defined for domains.

19.1 Domain Overview

There are three kinds of domain, distinguished by their subset dependencies: base domains, subdomains and sparse subdomains. A base domain describes an index set spanning one or more dimensions. A subdomain creates an index set that is a subset of the indices in a base domain or another subdomain. Sparse subdomains are subdomains which can represent sparse index subsets efficiently. Simple subdomains are subdomains that are not sparse. These relationships can be represented as follows:

domain—type:
  base—domain—type
  simple—subdomain—type
  sparse—subdomain—type

Domains can be further classified according to whether they are regular or irregular. A regular domain represents a rectangular iteration space and can have a compact representation whose size is independent of the number of indices. Rectangular domains, with the exception of sparse subdomains, are regular.

An irregular domain can store an arbitrary set of indices of an arbitrary but homogeneous index type. Irregular domains typically require space proportional to the number of indices being represented. All associative domain types and their subdomains (including sparse subdomains) are irregular. Sparse subdomains of regular domains are also irregular.

An index set can be either ordered or unordered depending on whether its members have a well-defined order relationship. All regular and enumerated domains are ordered. All other associative domains are unordered.

The type of a domain describes how a domain is represented and the operations that can be performed upon it, while its value is the set of indices it represents. In addition to storing a value, each domain variable has an identity that distinguishes it from other domains that may have the same type and value. This identity is used to define the domain’s relationship with subdomains, index types (§19.5), and arrays (§20.11).

Open issue. In the future, it is likely that we will support a means of creating domain aliases, much as we support array aliases currently.

The runtime representation of a domain is controlled by its domain map. Domain maps are presented in §27.
19.2 Base Domain Types and Values

Base domain types can be classified as regular or irregular. Dense and strided rectangular domains are regular domains. Irregular base domain types include all of the associative domain types.

Base domain:
rectangular domain
associative domain

These base domain types are discussed in turn in the following subsections.

19.2.1 Rectangular Domains

Rectangular domains describe multidimensional rectangular index sets. They are characterized by a tensor product of ranges and represent indices that are tuples of an integral type. Because their index sets can be represented using ranges, regular domain values typically require only $O(1)$ space.

Rectangular Domain Types

Rectangular domain types are parameterized by three things:

- `rank` a positive `int` value indicating the number of dimensions that the domain represents;
- `idxType` a type member representing the index type for each dimension; and
- `stridable` a `bool` parameter indicating whether any of the domain’s dimensions will be characterized by a strided range.

If `rank` is 1, the index type represented by a rectangular domain is `idxType`. Otherwise, the index type is the homogenous tuple type `rank*idxType`. If unspecified, `idxType` defaults to `int` and `stridable` defaults to `false`.

Open issue. We may represent a rectangular domain’s index type as `rank*idxType` even if rank is 1. This would eliminate a lot of code currently used to support the special (rank == 1) case.

The syntax of a rectangular domain type is summarized as follows:

```
rectangular–domain–type:
    domain ( named–expression–list )
```

where `named–expression–list` permits the values of `rank`, `idxType`, and `stridable` to be specified using standard type signature.

Example (typeFunctionDomain.chpl). The following declarations both create an uninitialized rectangular domain with three dimensions, with `int` indices:

```
var D1 : domain(rank=3, idxType=int, stridable=false);
var D2 : domain(3*int);
```
Rectangular Domain Values

Each dimension of a rectangular domain is a range of type \( \text{range}(\text{idxType}, \text{BoundedRangeType}.\text{bounded}, \text{stridable}) \). The index set for a rank 1 domain is the set of indices described by its singleton range. The index set for a rank \( n \) domain is the set of all \( n \cdot \text{idxType} \) tuples described by the tensor product of its ranges. When expanded (as by an iterator), rectangular domain indices are ordered according to the lexicographic order of their values. That is, the index with the highest rank is listed first and changes most slowly.\(^1\)

Future. Domains defined using unbounded ranges may be supported.

Literal rectangular domain values are represented by a comma-separated list of range expressions of matching \( \text{idxType} \) enclosed in curly braces:

\[
\text{rectangular-domain-literal:} \\
\{ \text{range-expression-list} \}
\]

\[
\text{range-expression-list:} \\
\text{range-expression} \\
\text{range-expression, range-expression-list}
\]

The type of a rectangular domain literal is defined as follows:

- \( \text{rank} \) = the number of range expressions in the literal;
- \( \text{idxType} \) = the type of the range expressions;
- \( \text{stridable} \) = \( \text{true} \) if any of the range expressions are stridable, otherwise \( \text{false} \).

If the index types in the ranges differ and all of them can be promoted to the same type, then that type is used as the \( \text{idxType} \). Otherwise, the domain literal is invalid.

Example. The expression \( \{1..5, 1..5\} \) defines a rectangular domain with type \( \text{domain}(\text{rank}=2, \text{idxType}=\text{int}, \text{stridable}=\text{false}) \). It is a \( 5 \times 5 \) domain with the indices:

\[
(1,1), (1,2), \ldots, (1,5), (2,1), \ldots (5,5).
\]

A domain expression may contain bounds which are evaluated at runtime.

Example. In the code

```plaintext
var D: domain(2) = {1..n, 1..n};
```

\( D \) is defined as a two-dimensional, nonstridable rectangular domain with an index type of \( 2\cdot\text{int} \) and is initialized to contain the set of indices \((i,j)\) for all \( i \) and \( j \) such that \( i \in 1,2,\ldots,n \) and \( j \in 1,2,\ldots,n \).

The default value of a range type is the \( \text{rank} \) default range values for type:

\(^1\)This is also known as row-major ordering.
Example (rectangularDomain.chpl). The following creates a two-dimensional rectangular domain and then uses this to declare an array. The array indices are iterated over using the domain's dim() method, and each element is filled with some value. Then the array is printed out.

Thus, the code

```chapel
var D : domain(2) = {1..2, 1..7};
var A : [D] int;
for i in D.dim(1) do
    for j in D.dim(2) do
        A[i,j] = 7 * i**2 + j;
writeln(A);
```

produces

```
8 9 10 11 12 13 14
29 30 31 32 33 34 35
```

19.2.2 Associative Domains

Associative domains represent an arbitrary set of indices of a given type and can be used to describe sets or to create dictionary-style arrays (hash tables). The type of indices of an associative domain, or its idxType, can be any primitive type except void or any class type.

Associative Domain Types

An associative domain type is parameterized by idxType, the type of the indices that it stores. The syntax is as follows:

```
associative-domain-type:
    domain ( associative-index-type )
    domain ( enum-type )
    domain ( opaque )

associative-index-type:
    type-specifier
```

The three expansions of `associative-domain-type` correspond to the three kinds of associative domain listed below.

1. In general, `associative-index-type` determines `idxType` of the associative domain type.
2. Enumerated domains are a special case, in which `idxType` is an enumerated type. Enumerated domains are handled specially during initialization and have a defined iteration order, as described below.
3. Opaque domains are a special case, indicated by the type `opaque`. Anonymous values of the type `opaque` are used as index values in this case.

When an associative domain is used as the index set of an array, the relation between the indices and the array elements can be thought of as a map between the values of the index set and the elements stored in the array. Opaque domains can be used to build unstructured arrays that are similar to pointer-based data structures in conventional languages.
Domains

Associative Domain Values

An associative domain’s value is simply the set of all index values that the domain describes. The iteration order over the indices of an associative domain is undefined, except for enumerated domains. The iteration order over the indices of an enumerated domain is the declaration order of the corresponding enumeration constants.

Specification of an associative domain literal value follows a similar syntax as rectangular domain literal values. What differentiates the two are the types of expressions specified in the comma separated list. Use of values of a type other than ranges will result in the construction of an associative domain.

\[
\text{associative-domain-literal:} \\
\{ \text{associative-expression-list} \}
\]

\[
\text{associative-expression-list:} \\
\text{non-range-expression} \\
\text{non-range-expression, associative-expression-list}
\]

\[
\text{non-range-expression:} \\
\text{expression}
\]

It is required that the types of the values used in constructing an associative domain literal value be of the same type. If the types of the indices does not match a compiler error will be issued.

*Future.* Due to implementation of \(==\) over arrays it is currently not possible to use arrays as indices within an associative domain.

*Open issue.* Assignment of an associative domain literal results in the a warning message being printed altering the user that whole-domain assignment has been serialized. This results from the resize operation over associative arrays not being parsafe.

*Example (associativeDomain.chpl).* The following example illustrates construction of an associative domain containing string indices "bar" and "foo". Note that due to internal hashing of indices the order in which the values of the associative domain are iterated is not the same as their specification order.

This code

\[
\text{var D : domain\{string\} = \{"bar", "foo"\};} \\
\text{writeln(D);} \\
\]

produces the output

\[
\{\text{foo, bar}\}
\]

If unspecified the default value of an associative domain type is the empty index set, except for enumerated domains. The default value of an enumerated domain type is the set of all constants of the corresponding enumerated type.

*Rationale.* The decision to have enumerated domains start fully populated was based on the observation that enumerations have a finite, typically small number of values and that it would be common to declare arrays with elements corresponding to each identifier in the enumeration. Further, in terms of usability it is simpler to clear a fully-populated domain than to fully populate an empty one.

In addition, fully-populated constant enumerated domains are an important case for compiler optimizations, particularly if the numeric values of the enumeration are consecutive.
Domains

Future. We may generally support a \texttt{startPopulated} parameter on associative domains, to unify this capability with other values.

Indices can be added to or removed from an associative domain as described in §19.8.5.

19.3 Simple Subdomain Types and Values

A subdomain is a domain whose indices are guaranteed to be a subset of those described by another domain known as its \textit{parent domain}. A subdomain has the same type as its parent domain, and by default it inherits the domain map of its parent domain. All domain types support subdomains.

Simple subdomains are subdomains which are not sparse. Sparse subdomains are discussed in the following section (§19.4). A simple subdomain inherits its representation (regular or irregular) from its base domain (or base subdomain). A sparse subdomain is always irregular, even if its base domain is regular.

In all other respects, the two kinds of subdomain behave identically. In this specification, “subdomain” refers to both simple and sparse subdomains, unless it is specifically distinguished as one or the other.

\textit{Rationale}. Subdomains are provided in Chapel for a number of reasons: to facilitate the ability of the compiler or a reader to reason about the inter-relationship of distinct domain variables; to support the author’s ability to omit redundant domain mapping specifications; to support the compiler’s ability to reason about the relative alignment of multiple domains; and to improve the compiler’s ability to prove away bounds checks for array accesses.

19.3.1 Simple Subdomain Types

A simple subdomain type is specified using the following syntax:

\begin{verbatim}
  simple-subdomain-type:
    subdomain ( domain-expression )
\end{verbatim}

This declares that \textit{domain-expression} is the parent domain of this subdomain type. A simple subdomain specifies a subdomain with the same underlying representation as its base domain.

\textit{Open issue.}

An open semantic issue for subdomains is when a subdomain’s subset property should be re-verified once its parent domain is reassigned and whether this should be done aggressively or lazily.

19.3.2 Simple Subdomain Values

The value of a simple subdomain is the set of all index values that the subdomain describes.

The default value of a simple subdomain type is the same as the default value of its parent’s type (§19.2.1 §19.2.2).

A simple subdomain variable can be initialized or assigned to with a tuple of values of the parent’s \texttt{idxType}. Indices can also be added to or removed from a simple subdomain as described in §19.8.5. It is an error to attempt to add an index to a subdomain that is not also a member of the parent domain.
19.4 Sparse Subdomain Types and Values

```
sparse-subdomain-type:
sparse subdomain_opt ( domain-expression )
```

This declaration creates a sparse subdomain. Sparse subdomains are irregular domains that describe an arbitrary subset of a domain, even if the parent domain is a regular domain. Sparse subdomains are useful in Chapel for defining sparse arrays in which a single element value (usually “zero”) occurs frequently enough that it is worthwhile to avoid storing it redundantly. The set difference between a sparse subdomain’s index set and that of parent domain is the set of indices for which the sparse array will store this replicated value. See §20.10 for details about sparse arrays.

19.4.1Sparse Subdomain Types

Each root domain type has a unique corresponding sparse subdomain type. Sparse subdomains whose parent domains are also sparse subdomains share the same type.

19.4.2Sparse Subdomain Values

A sparse subdomain’s value is simply the set of all index values that the domain describes. If the parent domain defines an iteration order over its indices, the sparse subdomain inherits that order.

There is no literal syntax for an sparse subdomain. However, a variable of a sparse subdomain type can be initialized using a tuple of values of the parent domain’s index type.

The default value for a sparse subdomain value is the empty set. This is true even if the parent domain is an enumerated domain.

Example. The following code declares a two-dimensional dense domain \( D \), followed by a two dimensional sparse subdomain of \( D \) named \( \text{SpS}D \). Since \( \text{SpS}D \) is uninitialized, it will initially describe an empty set of indices from \( D \).

```
const D: domain(2) = {1..n, 1..n};
var SpS: sparse subdomain(D);
```

19.5 Domain Index Types

Each domain value has a corresponding compiler-provided index type which can be used to represent values belonging to that domain’s index set. Index types are described using the following syntax:

```
index-type:
index ( domain-expression )
```
A variable with a given index type is constrained to take on only values available within the domain on which it is defined. This restriction allows the compiler to prove away the bound checking that code safety considerations might otherwise require. Due to the subset relationship between a base domain and its subdomains, a variable of an index type defined with respect to a subdomain is also necessarily a valid index into the base domain.

Since an index types are known to be legal for a given domain, it may also afford the opportunity to represent that index using an optimized format that doesn’t simply store the index variable’s value. This fact could be used to support accelerated access to arrays declared over that domain. For example, iteration over an index type could be implemented using memory pointers and strides, rather than explicitly calculating the offset of each index within the domain.

These potential optimizations may make it less expensive to index into arrays using index type variables of their domains or subdomains.

In addition, since an index type is associated with a specific domain or subdomain, it carries more semantic weight than a generic index. For example, one could iterate over a rectangular domain with integer bounds using an \texttt{int(n)} as the index variable. However, it would be more precise to use a variable of the domain’s index type.

An open issue for index types is what the semantics should be for an index type value that is live across a modification to its domain’s index set—particularly one that shrinks the index set. Our hypothesis is that most stored indices will either have short lifespans or belong to constant or monotonically growing domains. But these semantics need to be defined nevertheless.

19.6 Iteration Over Domains

All domains support iteration via standard \texttt{for}, \texttt{forall}, and \texttt{coforall} loops. These loops iterate over all of the indices that the domain describes. If the domain defines an iteration order of its indices, then the indices are visited in that order.

The type of the iterator variable for an iteration over a domain named \texttt{D} is that domain’s index type, \texttt{index(D)}.

19.7 Domains as Arguments

This section describes the semantics of passing domains as arguments to functions.

19.7.1 Formal Arguments of Domain Type

When a domain value is passed to a formal argument of compatible domain type by default intent, it is passed by reference in order to preserve the domain’s identity.
19.7.2 Domain Promotion of Scalar Functions

Domain values may be passed to a scalar function argument whose type matches the domain’s index type. This results in a promotion of the scalar function as defined in §25.4.

Example. Given a function `foo()` that accepts real floating point values and an associative domain `D` of type `domain(real)`, `foo` can be called with `D` as its actual argument which will result in the function being invoked for each value in the index set of `D`.

Example. Given an array `A` with element type `int` declared over a one-dimensional domain `D` with `idxType int`, the array elements can be assigned their corresponding index values by writing:

```
A = D;
```

This is equivalent to:

```
forall (a,i) in zip(A,D) do
a = i;
```

19.8 Domain Operations

Chapel supplies predefined operators and functions that can be used to manipulate domains. Unless otherwise noted, these operations are applicable to a domain of any type, whether a base domain or a subdomain.

19.8.1 Domain Assignment

All domain types support domain assignment.

```
domain-expression:
domain-literal
domain-name
domain-assignment-expression
domain-striding-expression
domain-slice-expression

domain-literal:
rectangular-domain-literal
associative-domain-literal

domain-assignment-expression:
domain-name = domain-expression

domain-name:
identifier
```

Domain assignment is by value and causes the target domain variable to take on the index set of the right-hand side expression. In practice, the right-hand side expression is often another domain value; a tuple of ranges (for regular domains); or a tuple of indices or a loop that enumerates indices (for irregular domains). If the domain variable being assigned was used to declare arrays, these arrays are reallocated as discussed in §20.11.
Example. The following three assignments show ways of assigning indices to a sparse domain, $SpsD$. The first assigns the domain two index values, $(1,1)$ and $(n,n)$. The second assigns the domain all of the indices along the diagonal from $(1,1), \ldots, (n,n)$. The third invokes an iterator that is written to yield indices read from a file named “inds.dat”. Each of these assignments has the effect of replacing the previous index set with a completely new set of values.

$$
SpsD = ((1,1), (n,n)); \\
SpsD = [i \text{ in } 1..n] \{i,i\}; \\
SpsD = \text{readIndicesFromFile}("inds.dat");
$$

19.8.2 Domain Striding

The `by` operator can be applied to a rectangular domain value in order to create a strided rectangular domain value. The right-hand operand to the `by` operator can either be an integral value or an integral tuple whose size matches the domain’s rank.

$$
domain-striding-expression:
\quad domain-expression by expression
$$

The type of the resulting domain is the same as the original domain but with `stridable` set to true. In the case of an integer stride value, the value of the resulting domain is computed by applying the integer value to each range in the value using the `by` operator. In the case of a tuple stride value, the resulting domain’s value is computed by applying each tuple component to the corresponding range using the `by` operator.

19.8.3 Domain Slicing

Slicing is the application of an index set to a domain. It can be written using either parentheses or square brackets. The index set can be defined with either a domain or a list of ranges.

$$
domain-slice-expression:
\quad domain-expression [ slicing-index-set ] \\
\quad domain-expression ( slicing-index-set )
$$

$$
slicing-index-set:
\quad domain-expression \\
\quad range-expression-list
$$

The result of slicing, or a slice, is a new domain value that represents the intersection of the index set of the domain being sliced and the index set being applied. The type and domain map of the slice match the domain being sliced.

Slicing can also be performed on an array, resulting in aliasing a subset of the array’s elements \(\text{(§20.6)}\).

Domain-based Slicing

If the brackets or parentheses contain a domain value, its index set is applied for slicing.

Open issue. Can we say that it is an alias in the case of sparse/associative?
Range-based Slicing

When slicing rectangular domains or arrays, the brackets or parentheses can contain a list of rank ranges. These ranges can either be bounded or unbounded. When unbounded, they inherit their bounds from the domain or array being sliced. The Cartesian product of the ranges’ index sets is applied for slicing.

Example. The following code declares a two dimensional rectangular domain \( D \), and then a number of subdomains of \( D \) by slicing into \( D \) using bounded and unbounded ranges. The \( \text{InnerD} \) domain describes the inner indices of \( D \), \( \text{Col2OfD} \) describes the 2nd column of \( D \), and \( \text{AllButLastRow} \) describes all of \( D \) except for the last row.

```c
const D: domain(2) = {1..n, 1..n},
    InnerD = D[2..n-1, 2..n-1],
    Col2OfD = D[.., 2..2],
    AllButLastRow = D[..n-1, ..];
```

Rank-Change Slicing

For multidimensional rectangular domains and arrays, substituting integral values for one or more of the ranges in a range-based slice will result in a domain or array of lower rank.

The result of a rank-change slice on an array is an alias to a subset of the array’s elements as described in §20.6.1.

The result of rank-change slice on a domain is a subdomain of the domain being sliced. The resulting subdomain’s type will be the same as the original domain, but with a rank equal to the number of dimensions that were sliced by ranges rather than integers.

19.8.4 Count Operator

The \# operator can be applied to dense rectangular domains with a tuple argument whose size matches the rank of the domain (or optionally an integer in the case of a 1D domain). The operator is equivalent to applying the \# operator to the component ranges of the domain and then using them to slice the domain as in Section 19.8.3.

19.8.5 Adding and Removing Domain Indices

All irregular domain types support the ability to incrementally add and remove indices from their index sets. This can either be done using \text{add(i:idxType)} and \text{remove(i:idxType)} methods on a domain variable or by using the \+= and \-= assignment operators. It is legal to add the same index to an irregular domain’s index set twice, but illegal to remove an index that does not belong to the domain’s index set.

Open issue. These remove semantics seem dangerous in a parallel context; maybe add flags to both the method versions of the call that say whether they should balk or not? Or add exceptions...

As with normal domain assignments, arrays declared in terms of a domain being modified in this way will be reallocated as discussed in §20.11.
19.9 Predefined Methods on Domains

This section gives a brief description of the library functions provided for Domains. These are categorized by the type of domain to which they apply: all, regular or irregular. Within each subsection, entries are listed in alphabetical order.

19.9.1 Methods on All Domain Types

The methods in this subsection can be applied to any domain.

**proc Domain.clear()**

Resets this domain’s index set to the empty set.

*Example (emptyEnumeratedDomain)*. In the case of an enumerated domain, this function provides a way to produce an empty index set.

When run, the code

```plaintext
enum Counter { one, two, three };
var D : domain ( Counter );
writeln("D has ", D.numIndices, " indices.");
D.clear();
writeln("D has ", D.numIndices, " indices.");
```

prints out

D has 3 indices.
D has 0 indices.

**proc Domain.idxType type**

Returns the domain type’s `idxType`. This function is not available on opaque domains.

**proc Domain.indexOrder(i: index(Domain)): idxType**

If `i` is a member of the domain, returns the ordinal value of `i` using a total ordering of the domain’s indices using 0-based indexing. Otherwise, it returns `(-1):idxType`. For rectangular domains, this ordering will be based on a row-major ordering of the indices; for other domains, the ordering may be implementation-defined and unstable as indices are added and removed from the domain.

**proc isEnumDom(d: domain) param**

Returns a param `true` if the given domain is enumerated, false otherwise.

**proc isIrregularDom(d: domain) param**

Returns a param `true` if the given domain is irregular, false otherwise.

**proc isOpaqueDom(d: domain) param**

Returns a param `true` if the given domain is opaque, false otherwise.

**proc isRectangularDom(d: domain) param**

Returns a param `true` if the given domain is rectangular, false otherwise.
Domains

Returns a param true if the given domain is rectangular, false otherwise.

proc isSparseDom(d: domain) param

Returns a param true if the given domain is sparse, false otherwise.

proc Domain.member(i)

Returns true if the given index i is a member of this domain’s index set, and false otherwise.

Open issue. We would like to call the type of i above idxType, but it’s not true for rectangular domains. That observation provides some motivation to normalize the behavior.

proc Domain.numIndices: capType

Returns the number of indices in the domain as a value of the capacity type.

19.9.2 Methods on Regular Domains

The methods described in this subsection can be applied to regular domains only.

proc Domain.dim(d: int): range

Returns the range of indices described by dimension d of the domain.

Example. In the code

for i in D.dim(1) do
  for j in D.dim(2) do
    writeln(A(i,j));

domain D is iterated over by two nested loops. The first dimension of D is iterated over in the outer loop. The second dimension is iterated over in the inner loop.

proc Domain.dims(): rank*range

Returns a tuple of ranges describing the dimensions of the domain.

proc Domain.expand(off: integral): domain
proc Domain.expand(off: rank*integral): domain

Returns a new domain that is the current domain expanded in dimension d if off or off(d) is positive or contracted in dimension d if off or off(d) is negative.

proc Domain.exterior(off: integral): domain
proc Domain.exterior(off: rank*integral): domain

Returns a new domain that is the exterior portion of the current domain with off or off(d) indices for each dimension d. If off or off(d) is negative, compute the exterior from the low bound of the dimension; if positive, compute the exterior from the high bound.

proc Domain.high: index(Domain)
Domains

Returns the high index of the domain as a value of the domain’s index type.

\[
\text{proc } \text{Domain.interior}(\text{off: integral}) : \text{domain} \\
\text{proc } \text{Domain.interior}(\text{off: rank}\times\text{integral}) : \text{domain}
\]

Returns a new domain that is the interior portion of the current domain with \text{off} or \text{off}(d) indices for each dimension \text{d}. If \text{off} or \text{off}(d) is negative, compute the interior from the low bound of the dimension; if positive, compute the interior from the high bound.

\[
\text{proc } \text{Domain.low} : \text{index(Domain)}
\]

Returns the low index of the domain as a value of the domain’s index type.

\[
\text{proc } \text{Domain.rank} \text{ param : int} \\
\text{Returns the rank of the domain.}
\]

\[
\text{proc } \text{Domain.size} : \text{capType} \\
\text{Same as } \text{Domain.numIndices}.
\]

\[
\text{proc } \text{Domain.strutsable} \text{ param : bool} \\
\text{Returns whether or not the domain is stridable.}
\]

\[
\text{proc } \text{Domain.stride} : \text{int(numBits(idxType)) where rank == 1} \\
\text{proc } \text{Domain.stride} : \text{rank}\times\text{int(numBits(idxType))}
\]

Returns the stride of the domain as the domain’s stride type (for 1D domains) or a tuple of the domain’s stride type (for multidimensional domains).

\[
\text{proc } \text{Domain.translate}(\text{off: integral}) : \text{domain} \\
\text{proc } \text{Domain.translate}(\text{off: rank}\times\text{integral}) : \text{domain}
\]

Returns a new domain that is the current domain translated by \text{off} or \text{off}(d) for each dimension \text{d}.

19.9.3 Methods on Irregular Domains

The following methods are available only on irregular domain types.

\[
\text{proc } + (\text{d: domain}, \text{i: index(d)}) \\
\text{proc } +(\text{i, d: domain}) \text{ where i: index(d)}
\]

Adds the given index to the given domain. If the given index is already a member of that domain, it is ignored.

\[
\text{proc } + (\text{d1: domain}, \text{d2: domain})
\]

Merges the index sets of the two domain arguments.

\[
\text{proc } - (\text{d: domain}, \text{i: index(d)})
\]

Removes the given index from the given domain. It is an error if the domain does not contain the given index.

\[
\text{proc } -(\text{d1: domain}, \text{d2: domain})
\]

Removes the indices in domain \text{d2} from those in \text{d1}. It is an error if \text{d2} contains indices which are not also in \text{d1}.

\[
\text{proc } \text{requestCapacity}(\text{s: int})
\]

Resizes the domain internal storage to hold at least \text{s} indicies.
20 Arrays

An array is a map from a domain’s indices to a collection of variables of homogenous type. Since Chapel domains support a rich variety of index sets, Chapel arrays are also richer than the traditional linear or rectilinear array types in conventional languages. Like domains, arrays may be distributed across multiple locales without explicitly partitioning them using Chapel’s Domain Maps (§27).

20.1 Array Types

An array type is specified by the identity of the domain that it is declared over and the element type of the array. Array types are given by the following syntax:

\[
\text{array-type:} \quad \text{[domain-expression] type-specifier}
\]

The domain-expression must specify a domain that the array can be declared over. If the domain-expression is a domain literal, the curly braces around the literal may be omitted.

Example (decls.chpl). In the code

```chapel
const D: domain(2) = {1..10, 1..10};
var A: [D] real;
```

A is declared to be an arithmetic array over rectangular domain D with elements of type real. As a result, it represents a 2-dimensional 10 × 10 real floating point variables indexed using the indices (1, 1), (1, 2), . . . , (1, 10), (2, 1), . . . , (10, 10).

An array’s element type can be referred to using the member symbol eltType.

Example (eltType.chpl). In the following example, x is declared to be of type real since that is the element type of array A.

```chapel
var A: [D] real;
var x: A.eltType;
```

20.2 Array Values

An array’s value is the collection of its elements’ values. Assignments between array variables are performed by value as described in §20.5. Chapel semantics are defined so that the compiler will never need to insert temporary arrays of the same size as a user array variable.

Array literal values can be either rectangular or associative, corresponding to the underlying domain which defines its indices.

\[
\text{array-literal:} \quad \text{rectangular-array-literal} \quad \text{associative-array-literal}
\]
20.2.1 Rectangular Array Literals

Rectangular array literals are specified by enclosing a comma separated list of expressions representing values in square brackets. A 1-based domain will automatically be generated for the given array literal. The type of the array’s values will be the type of the first element listed.

```
rectangular-array-literal:
  [ expression-list ]
```

**Example (decl-literal.chpl)**. The following example declares a 5 element rectangular array literal containing strings, then subsequently prints each string element to the console.

```
var A = ["1", "2", "3", "4", "5"];
for i in 1..5 do
  writeln(A[i]);
```

**Future**. Provide syntax which allows users to specify the domain for a rectangular array literal.

**Future**. Determine the type of a rectangular array literal based on the most promoted type, rather than the first element’s type.

**Example (decl-with-anon-domain.chpl)**. The following example declares a 2-element array `A` containing 3-element arrays of real numbers. `A` is initialized using array literals.

```
var A: [1..2] [1..3] real = [[[1.1, 1.2, 1.3], [2.1, 2.2, 2.3]]];
```

**Open issue**. We would like to differentiate syntactically between array literals for an array of arrays and a multi-dimensional array.

An rectangular array’s default value is for each array element to be initialized to the default value of the element type.

20.2.2 Associative Array Literals

Associative array values are specified by enclosing a comma separated list of index-to-value bindings within square brackets. It is expected that the indices in the listing match in type and, likewise, the types of values in the listing also match.

```
associative-array-literal:
  [ associative-expr-list ]
```

```
associative-expr-list:
  index-expr => value-expr
  index-expr => value-expr, associative-expr-list
```

```
index-expr:
  expression
```

```
value-expr:
  expression
```
Open issue. Currently it is not possible to use other associative domains as values within an associative array literal.

Example (adecl-assocLiteral.chpl). The following example declares a 5 element associative array literal which maps integers to their corresponding string representation. The indices and their corresponding values are then printed.

```chapl
var A = [1 => "one", 10 => "ten", 3 => "three", 16 => "sixteen"];
for da in zip (A.domain, A) do
  writeln(da);
```

### 20.2.3 Runtime Representation of Array Values

The runtime representation of an array in memory is controlled by its domain’s domain map. Through this mechanism, users can reason about and control the runtime representation of an array’s elements. See §27 for more details.

### 20.3 Array Indexing

Arrays can be indexed using index values from the domain over which they are declared. Array indexing is expressed using either parenthesis or square brackets. This results in a reference to the element that corresponds to the index value.

Example (array-indexing.chpl). Given:

```chapl
var A: [1..10] real;
```

the first two elements of A can be assigned the value 1.2 and 3.4 respectively using the assignment:

```chapl
A(1) = 1.2;
```

Except for associative arrays, if an array is indexed using an index that is not part of its domain’s index set, the reference is considered out-of-bounds and a runtime error will occur, halting the program.

#### 20.3.1 Rectangular Array Indexing

Since the indices for multidimensional rectangular domains are tuples, for convenience, rectangular arrays can be indexed using the list of integer values that make up the tuple index. This is semantically equivalent to creating a tuple value out of the integer values and using that tuple value to index the array. For symmetry, 1-dimensional rectangular arrays can be accessed using 1-tuple indices even though their index type is an integral value. This is semantically equivalent to de-tupling the integral value from the 1-tuple and using it to index the array.

Example (array-indexing-2.chpl). Given:
the elements of array A can be indexed using any of the following idioms:

\[
\begin{align*}
A(1j) &= 1.1; \\
A((1, 2)) &= 1.2; \\
A(1, 3) &= 1.3; \\
A[1j] &= -1.1; \\
A[(1, 4)] &= 1.4; \\
A[1, 5] &= 1.5;
\end{align*}
\]

Example (index-using-var-arg-tuple.chpl). The code

```chapel
proc f(A: [], is...) return A(is);
```

defines a function that takes an array as the first argument and a variable-length argument list. It then indexes into the array using the tuple that captures the actual arguments. This function works even for one-dimensional arrays because one-dimensional arrays can be indexed into by 1-tuples.

### 20.3.2 Associative Array Indexing

Indices can be added to associative arrays in two different ways.

The first way is through the array’s domain.

Example (assoc-add-index.chpl). Given:

```chapel
var D : domain(string);
var A : [D] int;
```

the array A initially contains no elements. We can change that by adding indices to the domain D:

```chapel
D.add("a");
D.add("b");
```

The array A can now be indexed with indices "a" and "b":

```chapel
A["a"] = 1;
A["b"] = 2;
var x = A["a"];```

The second way is more concise, and has the same effect as the first method:

Example (assoc-add-index-2.chpl).

```chapel
var D : domain(string);
var A : [D] int;
```

For other array types, assigning to an index not in the array’s domain would incur an out-of-bounds error. For associative arrays such assignment will add the index to the array’s domain, and the array can be indexed with the newly added indices:
A["a"] = 1;
A["b"] = 2;
var x = A["a"];

Here, the indices "a" and "b" are implicitly added the domain D. Reading from an index not in the array is still an out-of-bounds error.

// writeln(A["c"]); // halts if "c" is not in A’s domain

An important restriction for this method is that A may not share its domain with another array. This restriction exists because it may be surprising to seemingly modify one array, and to then see a change in another array. This restriction is checked at runtime.

20.4 Iteration over Arrays

All arrays support iteration via standard for, forall and coforall loops. These loops iterate over all of the array elements as described by its domain. A loop of the form:

\[
\text{[for|forall|coforall] } a \text{ in } A \text{ do }
\]

...a...

is semantically equivalent to:

\[
\text{[for|forall|coforall] } i \text{ in } A.\text{domain do }
\]

...A[i]...

The iterator variable for an array iteration is a reference to the array element type.

20.5 Array Assignment

Array assignment is by value. Arrays can be assigned arrays, ranges, domains, iterators, or tuples.

Example (assign.chpl). If A is an lvalue of array type and B is an expression of either array, range, or domain type, or an iterator, then the assignment

\[
A = B;
\]

is equivalent to

\[
\text{forall (a,b) in zip(A,B) do }
\]

a = b;

If the zipper iteration is illegal, then the assignment is illegal. Notice that the assignment is implemented with the semantics of a forall loop.

Arrays can be assigned tuples of values of their element type if the tuple contains the same number of elements as the array. For multidimensional arrays, the tuple must be a nested tuple such that the nesting depth is equal to the rank of the array and the shape of this nested tuple must match the shape of the array. The values are assigned element-wise.

Arrays can also be assigned single values of their element type. In this case, each element in the array is assigned this value.
Example (assign-2.chpl). If $e$ is an expression of the element type of the array or a type that can be implicitly converted to the element type of the array, then the assignment

$$A = e;$$

is equivalent to

```chpl
forall a in A do
    a = e;
```

### 20.6 Array Slicing

An array can be sliced using a domain that has the same type as the domain over which it was declared. The result of an array slice is an alias to the subset of the array elements from the original array corresponding to the slicing domain's index set.

Example (slicing.chpl). Given the definitions

```chpl
var OuterD: domain(2) = {0..n+1, 0..n+1};
var InnerD: domain(2) = {1..n, 1..n};
var A, B: [OuterD] real;
```

the assignment given by

```chpl
A[InnerD] = B[InnerD];
```

assigns the elements in the interior of $B$ to the elements in the interior of $A$.

#### 20.6.1 Rectangular Array Slicing

A rectangular array can be sliced by any rectangular domain that is a subdomain of the array’s defining domain. If the subdomain relationship is not met, an out-of-bounds error will occur. The result is a subarray whose indices are those of the slicing domain and whose elements are an alias of the original array’s.

Rectangular arrays also support slicing by ranges directly. If each dimension is indexed by a range, this is equivalent to slicing the array by the rectangular domain defined by those ranges. These range-based slices may also be expressed using partially unbounded or completely unbounded ranges. This is equivalent to slicing the array’s defining domain by the specified ranges to create a subdomain as described in §20.6 and then using that subdomain to slice the array.

#### 20.6.2 Rectangular Array Slicing with a Rank Change

For multidimensional rectangular arrays, slicing with a rank change is supported by substituting integral values within a dimension’s range for an actual range. The resulting array will have a rank less than the rectangular array’s rank and equal to the number of ranges that are passed in to take the slice.

Example (array-decl.chpl). Given an array

```chpl
var A: [1..n, 1..n] int;
```

the slice $A[1..n, 1]$ is a one-dimensional array whose elements are the first column of $A$. 
20.7 Count Operator

The `#` operator can be applied to dense rectangular arrays with a tuple argument whose size matches the rank of the array (or optionally an integer in the case of a 1D array). The operator is equivalent to applying the `#` operator to the array’s domain and using the result to slice the array as described in Section 20.6.1.

20.8 Array Arguments to Functions

Arrays are passed to functions by reference. Formal arguments that receive arrays are aliases of the actual arguments.

When a formal argument has array type, the element type of the array can be omitted and/or the domain of the array can be queried or omitted. In such cases, the argument is generic and is discussed in §22.1.6.

If a formal array argument specifies a domain as part of its type signature, the domain of the actual argument must represent the same index set. If the formal array’s domain was declared using an explicit domain map, the actual array’s domain must use an equivalent domain map.

20.8.1 Array Promotion of Scalar Functions

Array promotion of a scalar function is defined over the array type and the element type of the array. The domain of the returned array, if an array is captured by the promotion, is the domain of the array that promoted the function. In the event of zipper promotion over multiple arrays, the promoted function returns an array with a domain that is equal to the domain of the first argument to the function that enables promotion. If the first argument is an iterator or a range, the result is a one-based one-dimensional array.

*Example (whole-array-ops.chpl).* Whole array operations is a special case of array promotion of scalar functions. In the code

\[
A = B + C;
\]

if \(A, B,\) and \(C\) are arrays, this code assigns each element in \(A\) the element-wise sum of the elements in \(B\) and \(C\).

20.9 Array Aliases

Array slices alias the data in arrays rather than copying it. Such array aliases can be captured and optionally reindexed with the array alias operator `=>`. The syntax for capturing an alias to an array requires a new variable declaration:

```
array--alias--declaration:
  identifier reindexing--expressionopt ==> array--expression;

reindexing--expression:
  : [ domain--expression ]
```

array--expression:
  expression
Arrays

The identifier is an alias to the array specified in the array-expression.

The optional reindexing-expression allows the domain of the array alias to be reindexed. The shape of the domain in the reindexing-expression must match the shape of the domain of the array-expression. Indexing via the alias is governed by the new indices.

Example (reindexing.chpl). In the code

\[
\begin{align*}
\text{var} & \quad A: [1..5, 1..5] \text{ int}; \\
\text{var} & \quad AA: [0..2, 0..2] \Rightarrow A[2..4, 2..4];
\end{align*}
\]

an array alias AA is created to alias the interior of array A given by the slice A[2..4, 2..4]. The reindexing expression changes the indices defined by the domain of the alias to be zero-based in both dimensions. Thus AA(1,1) is equivalent to A(3,3).

20.10 Sparse Arrays

Sparse arrays in Chapel are those whose domain is a sparse array. A sparse array differs from other array types in that it stores a single value corresponding to multiple indices. This value is commonly referred to as the zero value, but we refer to it as the implicitly replicated value or IRV since it can take on any value of the array’s element type in practice including non-zero numeric values, a class reference, a record or tuple value, etc.

An array declared over a sparse domain can be indexed using any of the indices in the sparse domain’s parent domain. If it is read using an index that is not part of the sparse domain’s index set, the IRV value is returned. Otherwise, the array element corresponding to the index is returned.

Sparse arrays can only be written at locations corresponding to indices in their domain’s index set. In general, writing to other locations corresponding to the IRV value will result in a runtime error.

By default a sparse array’s IRV is defined as the default value for the array’s element type. The IRV can be set to any value of the array’s element type by assigning to a pseudo-field named IRV in the array.

Example (sparse-error.chpl). The following code example declares a sparse array, SpsA using the sparse domain SpsD (For this example, assume that n>1). Line 2 assigns two indices to SpsD’s index set and then lines 3–4 store the values 1.1 and 9.9 to the corresponding values of SpsA. The IRV of SpsA will initially be 0.0 since its element type is real. However, the fifth line sets the IRV to be the value 5.5, causing SpsA to represent the value 1.1 in its low corner, 9.9 in its high corner, and 5.5 everywhere else. The final statement is an error since it attempts to assign to SpsA at an index not described by its domain, SpsD.

\[
\begin{align*}
\text{var} & \quad SpsD: \text{ sparse subdomain}(D); \\
\text{var} & \quad SpsA: [SpsD] \text{ real}; \\
SpsD & = ((1,1), (n,n)); \\
SpsA(1,1) & = 1.1; \\
SpsA(n,n) & = 9.9; \\
SpsA.IRV & = 5.5; \\
SpsA(1,n) & = 0.0; \quad \text{// ERROR!}
\end{align*}
\]
20.11  Association of Arrays to Domains

When an array is declared, it is linked during execution to the domain identity over which it was declared. This linkage is invariant for the array’s lifetime and cannot be changed.

When indices are added or removed from a domain, the change impacts the arrays declared over this particular domain. In the case of adding an index, an element is added to the array and initialized to the IRV for sparse arrays, and to the default value for the element type for dense arrays. In the case of removing an index, the element in the array is removed.

When a domain is reassigned a new value, its arrays are also impacted. Values that correspond to indices in the intersection of the old and new domain are preserved in the arrays. Values that could only be indexed by the old domain are lost. Values that can only be indexed by the new domain have elements added to the new array, initialized to the IRV for sparse arrays, and to the element type’s default value for other array types.

For performance reasons, there is an expectation that a method will be added to domains to allow non-preserving assignment, i.e., all values in the arrays associated with the assigned domain will be lost. Today this can be achieved by assigning the array’s domain an empty index set (causing all array elements to be deallocated) and then re-assigning the new index set to the domain.

An array’s domain can only be modified directly, via the domain’s name or an alias created by passing it to a function via default intent. In particular, the domain may not be modified via the array’s .domain method, nor by using the domain query syntax on a function’s formal array argument (§22.1.6).

**Rationale.** When multiple arrays are declared using a single domain, modifying the domain affects all of the arrays. Allowing an array’s domain to be queried and then modified suggests that the change should only affect that array. By requiring the domain to be modified directly, the user is encouraged to think in terms of the domain distinctly from a particular array.

In addition, this choice has the beneficial effect that arrays declared via an anonymous domain have a constant domain. Constant domains are considered a common case and have potential compilation benefits such as eliminating bounds checks. Therefore making this convenient syntax support a common, optimizable case seems prudent.

20.12  Predefined Functions and Methods on Arrays

There is an expectation that this list of predefined methods will grow.

**proc** Array.eType **type**

    Returns the element type of the array.

**proc** Array.rank **param**

    Returns the rank of the array.

**proc** Array.domain: this.domain

    Returns the domain of the given array. This domain is constant, implying that the domain cannot be resized by assigning to its domain field, only by modifying the domain directly.
**Arrays**

**proc** `Array.numElements: this.domain.dim_type`

Returns the number of elements in the array.

**proc** `reshape(A: Array, D: Domain): Array`

Returns a copy of the array containing the same values but in the shape of the new domain. The number of indices in the domain must equal the number of elements in the array. The elements of the array are copied into the new array using the default iteration orders over both arrays.

**proc** `Array.size: this.domain.dim_type`

Same as `Array.numElements`. 
21 Iterators

An iterator is a function that can generate, or yield, multiple values (consecutively or in parallel) via its yield statements.

Open issue. The parallel iterator story is under development. It is expected that the specification will be expanded regarding parallel iterators soon.

21.1 Iterator Definitions

The syntax to declare an iterator is given by:

\[
\text{iterator-declaration-statement:} \\
\quad \text{privacy-specifier}_{\text{opt}}, \text{iter} \text{ iterator-name argument-list}_{\text{opt}} \text{ return-intent}_{\text{opt}} \text{ return-type}_{\text{opt}} \text{ where-clause}_{\text{opt}} \\
\quad \text{iterator-body}
\]

\[
\text{iterator-name:} \\
\quad \text{identifier}
\]

\[
\text{iterator-body:} \\
\quad \text{block-statement} \\
\quad \text{yield-statement}
\]

The syntax of an iterator declaration is similar to a procedure declaration, with some key differences:

- The keyword \text{iter} is used instead of the keyword \text{proc}.
- The name of the iterator cannot overload any operator.
- \text{yield} statements may appear in the body of an iterator, but not in a procedure.
- A \text{return} statement in the body of an iterator is not allowed to have an expression.

21.2 The Yield Statement

The yield statement can only appear in iterators. The syntax of the yield statement is given by

\[
\text{yield-statement:} \\
\quad \text{yield} \text{ expression ;}
\]
When an iterator is executed and a `yield` is encountered, the value of the yield expression is returned. However, the state of execution of the iterator is saved. On its next invocation, execution resumes from the point immediately following that `yield` statement and with the saved state of execution. A `yield` statement in a variable iterator must contain an lvalue expression.

When a `return` is encountered, the iterator finishes without yielding another index value. The `return` statements appearing in an iterator are not permitted to have a return expression. An iterator also completes after the last statement in the iterator is executed. An iterator need not contain any yield statements.

### 21.3 Iterator Calls

Iterators are invoked using regular call expressions:

```
iteratable-call-expression:

call-expression
```

All details of iterator calls, including argument passing, function resolution, the use of parentheses versus brackets to delimit the parameter list, and so on, are identical to procedure calls as described in Chapter 13. However, the result of an iterator call depends upon its context, as described below.

#### 21.3.1 Iterators in For and Forall Loops

When an iterator is accessed via a for or forall loop, the iterator is evaluated alongside the loop body in an interleaved manner. For each iteration, the iterator yields a value and the body is executed.

#### 21.3.2 Iterators as Arrays

If an iterator function is captured into a new variable declaration or assigned to an array, the iterator is iterated over in total and the expression evaluates to a one-dimensional arithmetic array that contains the values returned by the iterator on each iteration.

**Example (as-arrays.chpl)**. Given this iterator

```chapel
iter squares(n: int): int {
    for i in 1..n do
        yield i * i;
}
```

the expression `squares(5)` evaluates to

```
1 4 9 16 25
```
21.3.3 Iterators and Generics

An iterator call expression can be passed to a generic function argument that has neither a declared type nor default value (§22.1.3). In this case the iterator is passed without being evaluated. Within the generic function the corresponding formal argument can be used as an iterator, e.g., in for loops. The arguments to the iterator call expression, if any, are evaluated at the call site, i.e., prior to passing the iterator to the generic function.

21.3.4 Recursive Iterators

Recursive iterators are allowed. A recursive iterator invocation is typically made by iterating over it in a loop.

Example (recursive.chpl). A post-order traversal of a tree data structure could be written like this:

```chapel
iter postorder(tree: Tree): string {
  if tree != nil {
    for child in postorder(tree.left) do
      yield child;
    for child in postorder(tree.right) do
      yield child;
    yield tree.data;
  }
}
```

By contrast, using calls `postorder(tree.left)` and `postorder(tree.right)` as stand-alone statements would result in generating temporary arrays containing the outcomes of these recursive calls, which would then be discarded.

21.4 Parallel Iterators

Iterators used in explicit forall-statements or -expressions must be parallel iterators. Reductions, scans and promotion over serial iterators will be serialized.

Parallel iterators are defined for standard constructs in Chapel such as ranges, domains, and arrays, thereby allowing these constructs to be used with forall-statements and -expressions.

The left-most iterable expression in a forall-statement or -expression determines the number of tasks, the iterations each task executes, and the locales on which these tasks execute. For ranges, default domains, and default arrays, these values can be controlled via configuration constants (§25.6).

Domains and arrays defined using distributed domain maps will typically implement forall loops with multiple tasks on multiple locales. For ranges, default domains, and default arrays, all tasks are executed on the current locale.

A more detailed definition of parallel iterators is forthcoming.
22 Generics

Chapel supports generic functions and types that are parameterizable over both types and parameters. The generic functions and types look similar to non-generic functions and types already discussed.

22.1 Generic Functions

A function is generic if any of the following conditions hold:

- Some formal argument is specified with an intent of type or param.
- Some formal argument has no specified type and no default value.
- Some formal argument is specified with a queried type.
- The type of some formal argument is a generic type, e.g., List. Queries may be inlined in generic types, e.g., List(?eltType).
- The type of some formal argument is an array type where either the element type is queried or omitted or the domain is queried or omitted.

These conditions are discussed in the next sections.

22.1.1 Formal Type Arguments

If a formal argument is specified with intent type, then a type must be passed to the function at the call site. A copy of the function is instantiated for each unique type that is passed to this function at a call site. The formal argument has the semantics of a type alias.

Example (build2tuple.chpl). The following code defines a function that takes two types at the call site and returns a 2-tuple where the types of the components of the tuple are defined by the two type arguments and the values are specified by the types default values.

```chapel
proc build2Tuple(type t, type tt) {
  var x1: t;
  var x2: tt;
  return (x1, x2);
}
```

This function is instantiated with “normal” function call syntax where the arguments are types:

```chapel
var t2 = build2Tuple(int, string);
t2 = (1, "hello");
```
22.1.2 Formal Parameter Arguments

If a formal argument is specified with intent param, then a parameter must be passed to the function at the call site. A copy of the function is instantiated for each unique parameter that is passed to this function at a call site. The formal argument is a parameter.

Example (fillTuple.chpl). The following code defines a function that takes an integer parameter \( p \) at the call site as well as a regular actual argument of integer type \( x \). The function returns a homogeneous tuple of size \( p \) where each component in the tuple has the value of \( x \).

```chpl
proc fillTuple(param p: int, x: int) {
    var result: p*int;
    for param i in 1..p do
        result(i) = x;
    return result;
}
```

The function call `fillTuple(3, 3)` returns a 3-tuple where each component contains the value 3.

22.1.3 Formal Arguments without Types

If the type of a formal argument is omitted, the type of the formal argument is taken to be the type of the actual argument passed to the function at the call site. A copy of the function is instantiated for each unique actual type.

Example (fillTuple2.chpl). The example from the previous section can be extended to be generic on a parameter as well as the actual argument that is passed to it by omitting the type of the formal argument \( x \).

The following code defines a function that returns a homogeneous tuple of size \( p \) where each component in the tuple is initialized to \( x \):

```chpl
proc fillTuple(param p: int, x) {
    var result: p*x.type;
    for param i in 1..p do
        result(i) = x;
    return result;
}
```

In this function, the type of the tuple is taken to be the type of the actual argument. The call `fillTuple(3, 3.14)` returns a 3-tuple of real values \((3.14, 3.14, 3.14)\). The return type is \(\text{(real, real, real)}\).

22.1.4 Formal Arguments with Queried Types

If the type of a formal argument is specified as a queried type, the type of the formal argument is taken to be the type of the actual argument passed to the function at the call site. A copy of the function is instantiated for each unique actual type. The queried type has the semantics of a type alias.

Example (fillTuple3.chpl). The example from the previous section can be rewritten to use a queried type for clarity:

```chpl
proc fillTuple(param p: int, x: ?t) {
    var result: p*t;
    for param i in 1..p do
        result(i) = x;
    return result;
}
```
22.1.5 Formal Arguments of Generic Type

If the type of a formal argument is a generic type, the type of the formal argument is taken to be the type of the actual argument passed to the function at the call site with the constraint that the type of the actual argument is an instantiation of the generic type. A copy of the function is instantiated for each unique actual type.

Example. The following code defines a function writeTop that takes an actual argument that is a generic stack (see § 22.6) and outputs the top element of the stack. The function is generic on the type of its argument.

```plaintext
proc writeTop(s: Stack) {
    write(s.top.item);
}
```

Types and parameters may be queried from the top-level types of formal arguments as well. In the example above, the formal argument’s type could also be specified as Stack(?type) in which case the symbol type is equivalent to s.itemType.

Note that generic types which have default values for all of their generic fields, e.g. range, are not generic when simply specified and require a query to mark the argument as generic. For simplicity, the identifier may be omitted.

Example. The following code defines a class with a type field that has a default value. Function f is defined to take an argument of this class type where the type field is instantiated to the default. Function g, on the other hand, is generic on its argument because of the use of the question mark.

```plaintext
class C {
    type t - int;
}
proc f(c: C) {
    // c.type is always int
}
proc g(c: C(?)) {
    // c.type may not be int
}
```

The generic type may be specified with some queries and some exact values. These exact values result in implicit where clauses for the purpose of function resolution.

Example. Given the class definition

```plaintext
class C {
    type t;
    type tt;
}
```

then the function definition

```plaintext
proc f(c: C(?t, real)) {
    // body
}
```

is equivalent to
Generics

```chpl
proc f(c: C(?t,?tt)) where tt == real {
   // body
}
```

For tuples with query arguments, an implicit where clause is always created to ensure that the size of the actual tuple matches the implicitly specified size of the formal tuple.

**Example.** The function definition

```chpl
proc f(t: (?t, real)) {
   // body
}
```

is equivalent to

```chpl
proc f(t: (?t, ?tt)) where t.size == 2 && tt == real {
   // body
}
```

**Example (query.chpl).** Type queries can also be used to constrain the types of other function arguments and/or the return type. In this example, the type query on the first argument establishes type constraints on the other arguments and also determines the return type.

The code

```chpl
writeln(sumOfThree(1,2,3));
writeln(sumOfThree(4.0,5.0,3.0));
```

```chpl
proc sumOfThree(x: ?t, y: t, z: t): t {
   var sum: t;
   sum = x + y + z;
   return sum;
}
```

produces the output

6
12.0

The generic types `integral`, `numeric` and `enumerated` are generic types that can only be instantiated with, respectively, the signed and unsigned integral types, all of the numeric types, and enumerated types.

### 22.1.6 Formal Arguments of Generic Array Types

If the type of a formal argument is an array where either the domain or the element type is queried or omitted, the type of the formal argument is taken to be the type of the actual argument passed to the function at the call site. If the domain is omitted, the domain of the formal argument is taken to be the domain of the actual argument.

A queried domain may not be modified via the name to which it is bound (see §20.11 for rationale).
22.2 Function Visibility in Generic Functions

Function visibility in generic functions is altered depending on the instantiation. When resolving function calls made within generic functions, the visible functions are taken from any call site at which the generic function is instantiated for each particular instantiation. The specific call site chosen is arbitrary and it is referred to as the point of instantiation.

For function calls that specify the module explicitly (§12.4.3), an implicit use of the specified module exists at the call site.

Example (point-of-instantiation.chpl). Consider the following code which defines a generic function bar:

```chpl
module M1 {  
  record R {  
    var x: int;  
    proc foo() { }  
  }  
}  

module M2 {  
  proc bar(x) {  
    x.foo();  
  }  
}  

module M3 {  
  use M1, M2;  
  proc main() {  
    var r: R;  
    bar(r);  
  }  
}
```

In the function `main`, the variable `r` is declared to be of type `R` defined in module `M1` and a call is made to the generic function `bar` which is defined in module `M2`. This is the only place where `bar` is called in this program and so it becomes the point of instantiation for `bar` when the argument `x` is of type `R`. Therefore, the call to the `foo` method in `bar` is resolved by looking for visible functions from within `main` and going through the use of module `M1`.

If the generic function is only called indirectly through dynamic dispatch, the point of instantiation is defined as the point at which the derived type (the type of the implicit this argument) is defined or instantiated (if the derived type is generic).

Rationale. Visible function lookup in Chapel’s generic functions is handled differently than in C++’s template functions in that there is no split between dependent and independent types.

Also, dynamic dispatch and instantiation is handled differently. Chapel supports dynamic dispatch over methods that are generic in some of its formal arguments.

Note that the Chapel lookup mechanism is still under development and discussion. Comments or questions are appreciated.
22.3 Generic Types

Generic types are generic classes and generic records. A class or record is generic if it contains one or more generic fields. A generic field is one of:

- a specified or unspecified type alias,
- a parameter field, or
- a var or const field that has no type and no initialization expression.

For each generic field, the class or record is parameterized over:

- the type bound to the type alias,
- the value of the parameter field, or
- the type of the var or const field, respectively.

Correspondingly, the class or record is instantiated with a set of types and parameter values, one type or value per generic field.

22.3.1 Type Aliases in Generic Types

If a class or record defines a type alias, the class or record is generic over the type that is bound to that alias. Such a type alias is accessed as if it were a field; similar to a parameter field, it cannot be assigned except in its declaration.

The type alias becomes an argument with intent type to the compiler-generated constructor (§22.3.6) for its class or record. This makes the compiler-generated constructor generic. The type alias also becomes an argument with intent type to the type constructor (§22.3.4). If the type alias declaration binds it to a type, that type becomes the default for these arguments, otherwise they have no defaults.

The class or record is instantiated by binding the type alias to the actual type passed to the corresponding argument of a user-defined (§22.3.7) or compiler-generated constructor or type constructor. If that argument has a default, the actual type can be omitted, in which case the default will be used instead.

Example (NodeClass.chpl). The following code defines a class called Node that implements a linked list data structure. It is generic over the type of the element contained in the linked list.

class Node {
  type eltType;
  var data: eltType;
  var next: Node(eltType);
}

The call new Node(real, 3.14) creates a node in the linked list that contains the value 3.14. The next field is set to nil. The type specifier Node is a generic type and cannot be used to define a variable. The type specifier Node(real) denotes the type of the Node class instantiated over real. Note that the type of the next field is specified as Node(eltType); the type of next is the same type as the type of the object that it is a field of.
22.3.2 Parameters in Generic Types

If a class or record defines a parameter field, the class or record is generic over the value that is bound to that field. The parameter becomes an argument with intent `param` to the compiler-generated constructor (§22.3.6) for that class or record. This makes the compiler-generated constructor generic. The parameter also becomes an argument with intent `param` to the type constructor (§22.3.4). If the parameter declaration has an initialization expression, that expression becomes the default for these arguments, otherwise they have no defaults.

The class or record is instantiated by binding the parameter to the actual value passed to the corresponding argument of a user-defined (§22.3.7) or compiler-generated constructor or type constructor. If that argument has a default, the actual value can be omitted, in which case the default will be used instead.

*Example (IntegerTuple.chpl).* The following code defines a class called `IntegerTuple` that is generic over an integer parameter which defines the number of components in the class.

```chapel
class IntegerTuple {
    var size: int;
    var data: size* int;
}
```

The call `new IntegerTuple(3)` creates an instance of the `IntegerTuple` class that is instantiated over parameter 3. The field `data` becomes a 3-tuple of integers. The type of this class instance is `IntegerTuple(3)`. The type specified by `IntegerTuple` is a generic type.

22.3.3 Fields without Types

If a `var` or `const` field in a class or record has no specified type or initialization expression, the class or record is generic over the type of that field. The field becomes an argument with default intent to the compiler-generated constructor (§22.3.6). That argument has no specified type and no default value. This makes the compiler-generated constructor generic. The field also becomes an argument with `type` intent and no default to the type constructor (§22.3.4). Correspondingly, an actual value must always be passed to the default constructor argument and an actual type to the type constructor argument.

The class or record is instantiated by binding the type of the field to the type of the value passed to the corresponding argument of a user-defined (§22.3.7) or compiler-generated constructor (§22.3.6). When the type constructor is invoked, the class or record is instantiated by binding the type of the field to the actual type passed to the corresponding argument.

*Example (fieldWithoutType.chpl).* The following code defines another class called `Node` that implements a linked list data structure. It is generic over the type of the element contained in the linked list. This code does not specify the element type directly in the class as a type alias but rather omits the type from the `data` field.

```chapel
class Node {
    var data;
    var next: Node(data.type) = nil;
}
```

A node with integer element type can be defined in the call to the constructor. The call `new Node(1)` defines a node with the value 1. The code
```java
var list = new Node(1);
list.next = new Node(2);
```
defines a two-element list with nodes containing the values 1 and 2. The type of each object could be specified as Node(int).

### 22.3.4 The Type Constructor

A type constructor is automatically created for each class or record. A type constructor is a type function (§13.7.3) that has the same name as the class or record. It takes one argument per the class’s or record’s generic field, including fields inherited from the superclasses, if any. The formal argument has intent `type` for a type alias field and is a parameter for a parameter field. It accepts the type to be bound to the type alias and the value to be bound to the parameter, respectively. For a generic `var` or `const` field, the corresponding formal argument also has intent `type`. It accepts the type of the field, as opposed to a value as is the case for a parameter field. The formal arguments occur in the same order as the fields are declared and have the same names as the corresponding fields. Unlike the compiler-generated constructor, the type constructor has only those arguments that correspond to generic fields.

A call to a type constructor accepts actual types and parameter values and returns the type of the class or record that is instantiated appropriately for each field (§22.3.1, §22.3.2, §22.3.3). Such an instantiated type must be used as the type of a variable, array element, non-generic formal argument, and in other cases where uninstantiated generic class or record types are not allowed.

When a generic field declaration has an initialization expression or a type alias is specified, that initializer becomes the default value for the corresponding type constructor argument. Uninitialized fields, including all generic `var` and `const` fields, and unspecified type aliases result in arguments with no defaults; actual types or values for these arguments must always be provided when invoking the type constructor.

### 22.3.5 Generic Methods

All methods bound to generic classes or records, including constructors, are generic over the implicit `this` argument. This is in addition to being generic over any other argument that is generic.

### 22.3.6 The Compiler-Generated Constructor

If no user-defined constructors are supplied for a given generic class, the compiler generates one following in a manner similar to that for concrete classes (§15.3.2). However, the compiler-generated constructor for a generic class or record (§15.3.2) is generic over each argument that corresponds to a generic field, as specified above. The argument has intent `type` for a type alias field and is a parameter for a parameter field. It accepts the type to be bound to the type alias and the value to be bound to the parameter, respectively. This is the same as for the type constructor. For a generic `var` or `const` field, the corresponding formal argument has the default intent and accepts the value for the field to be initialized with. The type of the field is inferred automatically to be the type of the initialization value.

The default values for the generic arguments of the compiler-generated constructor are the same as for the type constructor (§22.3.4). For example, the arguments corresponding to the generic `var` and `const` fields, if any, never have defaults, so the corresponding actual values must always be provided.

22.3.7 User-Defined Constructors

If a generic field of a class does not have an initialization expression or a type alias is unspecified, each user-defined constructor for that class must provide a formal argument whose name matches the name of the field.

If the name of a formal argument in a user-defined constructor matches the name of a generic field that does not have an initialization expression, is a type alias, or is a parameter field, the field is automatically initialized at the beginning of the constructor invocation to the actual value of that argument. This is done by passing that formal argument to the implicit invocation of the compiler-generated constructor during default-initialization (§15.2.8).

Example (constructorsForGenericFields.chpl). In the following code:

```chapel
class MyGenericClass {
  type t1;
  param p1;
  const c1;
  var v1;
  var x1: t1; // this field is not generic

  type t5 = real;
  param p5 = "a string";
  const c5 = 5.5;
  var v5 = 555;
  var x5: t5; // this field is not generic

  proc MyGenericClass(c1, v1, type t1, param p1) { }
  proc MyGenericClass(type t5, param p5, c5, v5, x5,
      type t1, param p1, c1, v1, x1) { }
} // class MyGenericClass

var g1 = new MyGenericClass(11, 111, type t1, param p1);
var g2 = new MyGenericClass(type t5, param p5, c5, v5, x5,
      type t1, param p1, c1, v1, x1);
```

The arguments t1, p1, c1, and v1 are required in all constructors for MyGenericClass. They can appear in any order. Both MyGenericClass constructors initialize the corresponding fields implicitly because these fields do not have initialization expressions. The second constructor also initializes implicitly the fields t5 and p5 because they are a type field and a parameter field. It does not initialize the fields c5 and v5 because they have initialization expressions, or the fields x1 and x5 because they are not generic fields (even though they are of generic types).

Open issue. The design of constructors, especially for generic classes, is under development, so the above specification may change.

22.4 Where Expressions

The instantiation of a generic function can be constrained by where clauses. A where clause is specified in the definition of a function (§13.2). When a function is instantiated, the expression in the where clause must be a parameter expression and must evaluate to either true or false. If it evaluates to false, the instantiation is rejected and the function is not a possible candidate for function resolution. Otherwise, the function is instantiated.

Example (whereClause.chpl). Given two overloaded function definitions

```chapel
var q1 = new MyGenericClass(11, 111, int, 1);
var q2 = new MyGenericClass(int, "this is q2", 3.3, 333, 3333,
      real, 2, 222, 222.2, 22);
```
Generics

```chapel
proc foo(x) where x.type == int { writeln("int"); }
proc foo(x) where x.type == real { writeln("real"); }
```

the call foo(3) resolves to the first definition because when the second function is instantiated the where clause evaluates to false.

### 22.5 User-Defined Compiler Diagnostics

The special compiler diagnostic function calls `compilerError` and `compilerWarning` generate compiler diagnostic of the indicated severity if the function containing these calls may be called when the program is executed and the function call is not eliminated by parameter folding.

The compiler diagnostic is defined by the actual arguments which must be string parameters. The diagnostic points to the spot in the Chapel program from which the function containing the call is called. Compilation halts if a `compilerError` is encountered whereas it will continue after encountering a `compilerWarning`.

#### Cray’s Chapel Implementation

Note that when a function with a `ref` return intent is called in a context where the implicit `setter` argument is true or false, both versions of the function are resolved by the compiler. Consequently, the `setter` argument cannot be effectively used to guard a compiler diagnostic statements.

**Example (compilerDiagnostics.chpl)**. The following code shows an example of using user-defined compiler diagnostics to generate warnings and errors:

```chapel
proc foo(x, y) {
    if (x.type != y.type)
        compilerError("foo() called with non-matching types: ",
                       toString(x.type), " != ", toString(y.type));
    writeln("In 2-argument foo...");
}
proc foo(x) {
    compilerWarning("1-argument version of foo called");
    writeln("In generic foo!");
}
```

The first routine generates a compiler error whenever the compiler encounters a call to it where the two arguments have different types. It prints out an error message indicating the types of the arguments. The second routine generates a compiler warning whenever the compiler encounters a call to it.

Thus, if the program foo.chpl contained the following calls:

```chapel
1 foo(3.4);
2 foo("hi");
3 foo(1, 2);
4 foo(1.2, 3.4);
5 foo("hi", "bye");
6 foo(1, 2.3);
7 foo("hi", 2.3);
```

compiling the program would generate output like:

```
foo.chpl:1: warning: 1-argument version of foo called with type: real
foo.chpl:2: warning: 1-argument version of foo called with type: string
foo.chpl:6: error: foo() called with non-matching types: int != real
```
22.6 Example: A Generic Stack

Example (genericStack.chpl).

class MyNode {
    type itemType; // type of item
    var item: itemType; // item in node
    var next: MyNode(itemType); // reference to next node (same type)
}

record Stack {
    type itemType; // type of items
    var top: MyNode(itemType); // top node on stack linked list

    proc push(item: itemType) {
        top = new MyNode(itemType, item, top);
    }

    proc pop() {
        if isEmpty then
            halt("attempt to pop an item off an empty stack");
            var oldTop = top;
            top = top.next;
            return oldTop.item;
        }

        proc isEmpty return top == nil;
    }
}
23 Input and Output

23.1 See Library Documentation

24 Task Parallelism and Synchronization

Chapel supports both task parallelism and data parallelism. This chapter details task parallelism as follows:

- §24.1 introduces tasks and task parallelism.
- §24.2 describes the begin statement, an unstructured way to introduce concurrency into a program.
- §24.3 describes synchronization variables, an unstructured mechanism for synchronizing tasks.
- §24.4 describes atomic variables, a mechanism for supporting atomic operations.
- §24.5 describes the cobegin statement, a structured way to introduce concurrency into a program.
- §24.6 describes the coforall loop, another structured way to introduce concurrency into a program.
- §24.7 specifies how variables from outer scopes are handled within begin, cobegin and coforall statements.
- §24.8 describes the sync statement, a structured way to control parallelism.
- §24.9 describes the serial statement, a structured way to suppress parallelism.
- §24.10 describes the atomic statement, a construct to support atomic transactions.

24.1 Tasks and Task Parallelism

A Chapel task is a distinct context of execution that may be running concurrently with other tasks. Chapel provides a simple construct, the begin statement, to create tasks, introducing concurrency into a program in an unstructured way. In addition, Chapel introduces two type qualifiers, sync and single, for synchronization between tasks.

Chapel provides two constructs, the cobegin and coforall statements, to introduce concurrency in a more structured way. These constructs create multiple tasks but do not continue until these tasks have completed. In addition, Chapel provides two constructs, the sync and serial statements, to insert synchronization and suppress parallelism. All four of these constructs can be implemented through judicious uses of the unstructured task-parallel constructs described in the previous paragraph.

Tasks are considered to be created when execution reaches the start of a begin, cobegin, or coforall statement. When the tasks are actually executed depends on the Chapel implementation and run-time execution state.

A task is represented as a call to a task function, whose body contains the Chapel code for the task. Variables defined in outer scopes are considered to be passed into a task function by default intent, unless a different task intent is specified explicitly by a task-intent-clause.
24.2 The Begin Statement

The begin statement creates a task to execute a statement. The syntax for the begin statement is given by

\[
\text{begin-statement:} \\
\text{\hspace{1em} begin task-intent-clause_{opt} statement}
\]

Control continues concurrently with the statement following the begin statement.

Example (beginUnordered.chpl). The code

```chapel
begin writeln("output from spawned task"); writeln("output from main task");
```

executes two writeln statements that output the strings to the terminal, but the ordering is purposely unspecified. There is no guarantee as to which statement will execute first. When the begin statement is executed, a new task is created that will execute the writeln statement within it. However, execution will continue immediately after task creation with the next statement.

A begin statement creates a single task function, whose body is the body of the begin statement. The handling of the outer variables within the task function and the role of task-intent-clause are defined in §24.7.

Yield and return statements are not allowed in begin blocks. Break and continue statements may not be used to exit a begin block.

24.3 Synchronization Variables

Synchronization variables have a logical state associated with the value. The state of the variable is either full or empty. Normal reads of a synchronization variable cannot proceed until the variable’s state is full. Normal writes of a synchronization variable cannot proceed until the variable’s state is empty.

Chapel supports two types of synchronization variables: sync and single. Both types behave similarly, except that a single variable may only be written once. Consequently, when a sync variable is read, its state transitions to empty, whereas when a single variable is read, its state does not change. When either type of synchronization variable is written, its state transitions to full.

```
sync and single are type qualifiers and precede the type of the variable’s value in the declaration. Sync and single are supported for all Chapel primitive types (§7.1) except strings and complex.
```

If a task attempts to read or write a synchronization variable that is not in the correct state, the task is suspended. When the variable transitions to the correct state, the task is resumed. If there are multiple tasks blocked waiting for the state transition, one is non-deterministically selected to proceed and the others continue to wait if it is a sync variable; all tasks are selected to proceed if it is a single variable.

A synchronization variable is specified with a sync or single type given by the following syntax:
Task Parallelism and Synchronization

**sync-type:**
- **sync type-specifier**

**single-type:**
- **single type-specifier**

If a synchronization variable declaration has an initialization expression, then the variable is initially full, otherwise it is initially empty.

**Example (beginWithSyncVar.chpl).** The code

```chapel
class Tree {
  var isLeaf: bool;
  var left, right: Tree;
  var value: int;

  proc sum(): int {
    if (isLeaf) then
      return value;
    var x$: sync int;
    begin
      x$ = left.sum();
      var y = right.sum();
      return x$ + y;
    }
  }
}
```

the sync variable x$ is assigned by an asynchronous task created with the begin statement. The task returning the sum waits on the reading of x$ until it has been assigned. By convention, synchronization variables end in $ to provide a visual cue to the programmer indicating that the task may block.

**Example (syncCounter.chpl).** Sync variables are useful for tallying data from multiple tasks as well. If all updates to an initialized sync variable are via compound assignment operators (or equivalently, traditional assignments that read and write the variable once), the full/empty state of the sync variable guarantees that the reads and writes will be interleaved in a manner that makes the updates atomic. For example, the code:

```chapel
var count$: sync int = 0;
cobegin {
  count$ += 1;
  count$ += 1;
  count$ += 1;
}
```

creates three tasks that increment count$. If count$ were not a sync variable, this code would be unsafe because two tasks could then read the same value before either had written its updated value, causing one of the increments to be lost.

**Example (singleVar.chpl).** The following code implements a simple split-phase barrier using a single variable.

```chapel
var count$: sync int = n; // counter which also serves as a lock
var release$: single bool; // barrier release
forall t in 1..n do begin {
  work(t);
```
In each iteration of the forall loop after the work is completed, the task reads the `count$` variable, which is used to tally the number of tasks that have arrived. All tasks except the last task to arrive will block while trying to read the variable `release$`. The last task to arrive will write to `release$`, setting its state to full at which time all the other tasks can be unblocked and run.

If a formal argument with a default intent either has a synchronization type or the formal is generic ([22.1.5](#)) and the actual has a synchronization type, the actual must be an lvalue and is passed by reference. In these cases the formal itself is an lvalue, too. The actual argument is not read or written during argument passing; its state is not changed or waited on. The qualifier `sync` or `single` without the value type can be used to specify a generic formal argument that requires a `sync` or `single` actual.

When the actual argument is a `sync` or `single` and the corresponding formal has the actual’s base type or is implicitly converted from that type, a normal read of the actual is performed when the call is made, and the read value is passed to the formal.

### 24.3.1 Predefined Single and Sync Methods

The following methods are defined for variables of sync and single type.

```plaintext
proc (sync t).readFE(): t

Returns the value of the sync variable. This method blocks until the sync variable is full. The state of the sync variable is set to empty when this method completes. This method implements the normal read of a `sync` variable.

proc (sync t).readFF(): t
proc (single t).readFF(): t

Returns the value of the sync or single variable. This method blocks until the sync or single variable is full. The state of the sync or single variable remains full when this method completes. This method implements the normal read of a `single` variable.

proc (sync t).readXX(): t
proc (single t).readXX(): t

Returns the value of the sync or single variable. This method is non-blocking and the state of the sync or single variable is unchanged when this method completes.

proc (sync t).writeEF(v: t)
proc (single t).writeEF(v: t)
```
Assigns \( v \) to the value of the sync or single variable. This method blocks until the sync or single variable is empty. The state of the sync or single variable is set to full when this method completes. This method implements the normal write of a sync or single variable.

\[
\text{proc } (\text{sync } t)\text{.writeFF}(v: t)
\]
Assigns \( v \) to the value of the sync variable. This method blocks until the sync variable is full. The state of the sync variable remains full when this method completes.

\[
\text{proc } (\text{sync } t)\text{.writeXF}(v: t)
\]
Assigns \( v \) to the value of the sync variable. This method is non-blocking and the state of the sync variable is set to full when this method completes.

\[
\text{proc } (\text{sync } t)\text{.reset}()
\]
Assigns the default value of type \( t \) to the value of the sync variable. This method is non-blocking and the state of the sync variable is set to empty when this method completes.

\[
\text{proc } (\text{sync } t)\text{.isFull}: \text{bool} \\
\text{proc } (\text{single } t)\text{.isFull}: \text{bool}
\]
Returns true if the sync or single variable is full and false otherwise. This method is non-blocking and the state of the sync or single variable is unchanged when this method completes.

Note that writeEF and readFE/readFF methods (for sync and single variables, respectively) are implicitly invoked for normal writes and reads of synchronization variables.

*Example (syncMethods.chpl).* Given the following declarations

\[
\text{var } x$: \text{sync int} \\
\text{var } y$: \text{single int} \\
\text{var } z: \text{int}
\]
the code

\[
x$ = 5; \\
y$ = 6; \\
z = x$ + y$
\]

is equivalent to

\[
x$.\text{writeEF}(5); \\
y$.\text{writeEF}(6); \\
z = x$.\text{readFE}() + y$.\text{readFF}();
\]
24.4 Atomic Variables

Atomic variables are variables that support atomic operations. Chapel currently supports atomic operations for bools, all supported sizes of signed and unsigned integers, as well as all supported sizes of reals.

Rationale. The choice of supported atomic variable types as well as the atomic operations was strongly influenced by the C11 standard.

Atomic is a type qualifier that precedes the variable’s type in the declaration. Atomic operations are supported for bools, and all sizes of ints, uints, and reals.

An atomic variable is specified with an atomic type given by the following syntax:

\[ \text{atomic-type:} \quad \text{atomic type-specifier} \]

24.4.1 Predefined Atomic Methods

The following methods are defined for variables of atomic type. Note that not all operations are supported for all atomic types. The supported types are listed for each method.

Most of the predefined atomic methods accept an optional argument named order of type memory_order. The order argument is used to specify the ordering constraints of atomic operations. The supported memory_order values are:

- memory_order relaxed
- memory_order acquire
- memory_order release
- memory_order acq_rel
- memory_order seq_cst

Open issue. The memory_order values were taken directly from the C11 specification. We expect to review and better define the supported values with work on Chapel’s memory consistency model (sec 29).

Unless specified, the default for the memory_order parameter is memory_order_seq_cst.

Implementors’ note. Not all architectures or implementations may support all memory_order values. In these cases, the implementation should default to a more conservative ordering than specified.

\[ \text{proc (atomic t).read(memory_order order): t} \]

Reads and returns the stored value. Defined for all atomic types.

\[ \text{proc (atomic t).peek(): t} \]
Reads and returns the stored value using memory_order_relaxed. Defined for all atomic types.

```haskell
proc (atomic t).write(v: t, memory_order order)
```
Stores v as the new value. Defined for all atomic types.

```haskell
proc (atomic t).poke(v: t)
```
Stores v as the new value using memory_order_relaxed. Defined for all atomic types.

```haskell
proc (atomic t).exchange(v: t, memory_order order): t
```
Stores v as the new value and returns the original value. Defined for all atomic types.

```haskell
proc (atomic t).compareExchangeWeak(e: t, v: t, memory_order order): bool
proc (atomic t).compareExchangeStrong(e: t, v: t, memory_order order): bool
```
Stores v as the new value, if and only if the original value is equal to e. Returns true if v was stored, false otherwise. The 'weak' variation may return false even if the original value was equal to e, if, for example, the value could not be updated atomically. compareExchange is equivalent to compareExchangeStrong. Defined for all atomic types.

```haskell
proc (atomic t).add(v: t, memory_order order)
proc (atomic t).sub(v: t, memory_order order)
proc (atomic t).or(v: t, memory_order order)
proc (atomic t).and(v: t, memory_order order)
proc (atomic t).xor(v: t, memory_order order)
```
Applies the appropriate operator (+, −, |, &, ^) to the original value and v and stores the result. All of the methods are defined for integral atomic types. Only add and sub (+, −) are defined for real atomic types. None of the methods are defined for the bool atomic type.

```haskell
proc (atomic bool).testAndSet(memory_order order): bool
```
Stores true as the new value and returns the old value. Equivalent to exchange(true). Only defined for the bool atomic type.

```haskell
proc (atomic bool).clear(memory_order order)
```
Stores false as the new value. Equivalent to write(false). Only defined for the bool atomic type.

```haskell
proc (atomic t).waitFor(v: t)
```
Waits until the stored value is equal to v. The implementation may yield the running task while waiting. Defined for all atomic types.

Future. In the future we may overload certain operations such as += to call the above methods automatically for atomic variables.

```haskell
proc (atomic t).fetchAdd(v: t, memory_order order): t
proc (atomic t).fetchSub(v: t, memory_order order): t
proc (atomic t).fetchOr(v: t, memory_order order): t
proc (atomic t).fetchAnd(v: t, memory_order order): t
proc (atomic t).fetchXor(v: t, memory_order order): t
```
Applies the appropriate operator (+, −, |, &, ^) to the original value and v, stores the result, and returns the original value. All of the methods are defined for integral atomic types. Only add and sub (+, −) are defined for real atomic types. None of the methods are defined for the bool atomic type.
24.5 The Cobegin Statement

The cobegin statement is used to introduce concurrency within a block. The cobegin statement syntax is

\[
\text{cobegin-statement:} \\
\quad \text{cobegin task-intent-clause}_{opt} \text{ block-statement}
\]

A new task and a corresponding task function are created for each statement in the block-statement. Control continues when all of the tasks have finished. The handling of the outer variables within each task function and the role of task-intent-clause are defined in \(\text{§24.7}\). Return statements are not allowed in cobegin blocks. Yield statement may only be lexically enclosed in cobegin blocks in parallel iterators (\(\text{§21.4}\)). Break and continue statements may not be used to exit a cobegin block.

Example (cobeginAndEquivalent.chpl). The cobegin statement

\[
\text{cobegin} \\
\quad \{ \\
\quad \text{stmt1();} \\
\quad \text{stmt2();} \\
\quad \text{stmt3();} \\
\quad \}
\]

is equivalent to the following code that uses only begin statements and single variables to introduce concurrency and synchronize:

\[
\text{var s1$, s2$, s3$: single bool;} \\
\text{begin} \{ \text{stmt1(); s1$ = true;} \} \\
\text{begin} \{ \text{stmt2(); s2$ = true;} \} \\
\text{begin} \{ \text{stmt3(); s3$ = true;} \} \\
\text{s1$; s2$; s3$;}
\]

Each begin statement is executed concurrently but control does not continue past the final line above until each of the single variables is written, thereby ensuring that each of the functions has finished.

24.6 The Coforall Loop

The coforall loop is a variant of the cobegin statement in loop form. The syntax for the coforall loop is given by

\[
\text{coforall-statement:} \\
\quad \text{coforall index-var-declaration in iterable-expression task-intent-clause}_{opt} \text{ do statement} \\
\quad \text{coforall index-var-declaration in iterable-expression task-intent-clause}_{opt} \text{ block-statement} \\
\quad \text{coforall iterable-expression task-intent-clause}_{opt} \text{ do statement} \\
\quad \text{coforall iterable-expression task-intent-clause}_{opt} \text{ block-statement}
\]

The coforall loop creates a separate task for each iteration of the loop. Control continues with the statement following the coforall loop after all tasks corresponding to the iterations of the loop have completed.

The single task function created for a coforall and invoked by each task contains the loop body. The handling of the outer variables within the task function and the role of task-intent-clause are defined in \(\text{§24.7}\). Return statements are not allowed in coforall blocks. Yield statement may only be lexically enclosed in coforall blocks in parallel iterators (\(\text{§21.4}\)). Break and continue statements may not be used to exit a coforall block.
**Example (coforallAndEquivalent.chpl).** The coforall statement

```chpl
coforall i in iterator() {
    body();
}
```

is equivalent to the following code that uses only begin statements and sync and single variables to introduce concurrency and synchronize:

```chpl
var runningCount$: sync int = 1;
var finished$: single bool;
for i in iterator() {
    runningCount$ += 1;
    begin {
        body();
        var tmp = runningCount$;
        runningCount$ = tmp-1;
        if tmp == 1 then finished$ = true;
    }
    var tmp = runningCount$;
    runningCount$ = tmp-1;
    if tmp == 1 then finished$ = true;
    finished$;
}
```

Each call to `body()` executes concurrently because it is in a begin statement. The sync variable `runningCount$` is used to keep track of the number of executing tasks plus one for the main task. When this variable reaches zero, the single variable `finished$` is used to signal that all of the tasks have completed. Thus control does not continue past the last line until all of the tasks have completed.

### 24.7 Task Intents

If a variable is referenced within the lexical scope of a `begin`, `cobegin`, or `coforall` statement and is declared outside that statement, it is considered to be passed as an actual argument to the corresponding task function at task creation time. All references to the variable within the task function implicitly refer to the task function’s corresponding formal argument.

Each formal argument of a task function has the default intent by default. For variables of primitive and class types, this has the effect of capturing the value of the variable at task creation time and referencing that value instead of the original variable within the lexical scope of the task construct.

A formal can be given another intent explicitly by listing it with that intent in the optional `task-intent-clause`. For example, for variables of most types, the `ref` intent allows the task construct to modify the corresponding original variable or to read its updated value after concurrent modifications.

The syntax of the task intent clause is:

```chpl
task-intent-clause:
    with ( task-intent-list )

task-intent-list:
    formal-intent identifier
    formal-intent identifier, task-intent-list
```

**Task Parallelism and Synchronization** 195
where the following intents can be used as a formal-intent: ref, in, const, const in, const ref.

The implicit treatment of outer scope variables as the task function’s formal arguments applies to both module level
and local variables. It applies to variable references within the lexical scope of a task construct, but does not extend
to its dynamic scope, i.e., to the functions called from the task(s) but declared outside of the lexical scope. The loop
index variables of a coforall statement are not subject to such treatment within that statement; however, they are
subject to such treatment within nested task constructs, if any.

**Rationale.** The primary motivation for task intents is to avoid some races on scalar/record variables,
which are possible when one task modifies a variable and another task reads it. Without task intents, for
example, it would be easy to introduce and overlook a bug illustrated by this simplified example:

```plaintext
{
  var i = 0;
  while i < 10 {
    begin {
      f(i);
    }
    i += 1;
  }
}
```

If all the tasks created by the `begin` statement start executing only after the `while` loop completes, and
i within the `begin` is treated as a reference to the original i, there will be ten tasks executing f(10). However, the user most likely intended to generate ten tasks executing f(0), f(1), ..., f(9). Task intents
ensure that, regardless of the timing of task execution.

Another motivation for task intents is that referring to a captured copy in a task is often more efficient than
referring to the original variable. That’s because the copy is a local constant, e.g. it could be placed in a
register when it fits. Without task intents, references to the original variable would need to be implemented
using a pointer dereference. This is less efficient and can hinder optimizations in the surrounding code,
for example loop-invariant code motion.

Furthermore, in the above example the scope where i is declared may exit before all the ten tasks com-
plete. Without task intents, the user would have to protect i to make sure its lexical scope doesn’t exit
before the tasks referencing it complete.

We decided to treat `cobegin` and `coforall` statements the same way as `begin`. This is for consistency
and to make the race-avoidance benefit available to more code.

We decided to apply task intents to module level variables, in addition to local variables. Again, this is for
consistency. One could view module level variables differently than local variables (e.g. a module level
variable is “always available”), but we favored consistency over such an approach.

We decided not to apply task intents to “closure” variables, i.e., the variables in the dynamic scope of a
task construct. This is to keep this feature manageable, so that all variables subject to task intents can be
obtained by examining just the lexical scope of the task construct. In general, the set of closure variables
can be hard to determine, unwieldy to implement and reason about, it is unclear what to do with extern
functions, etc.

We do not provide `inout` or `out` as task intents because they will necessarily create a data race in a
cobegin or coforall. `type` and `param` intents are not available either as they do not seem useful as
task intents.

**Future.** For a given intent, we would also like to provide a blanket clause, which would apply the intent
to all variables. An example of syntax for a blanket `ref` intent would be `ref *`. 
24.8 The Sync Statement

The sync statement acts as a join of all dynamically encountered begins from within a statement. The syntax for the sync statement is given by

\[
\text{sync \text{-} statement:} \\
\text{sync \ statement} \\
\text{sync block\text{-}statement}
\]

Return statements are not allowed in sync statement blocks. Yield statement may only be lexically enclosed in sync statement blocks in parallel iterators (§21.4). Break and continue statements may not be used to exit a sync statement block.

*Example (syncStmt1.chpl)*. The sync statement can be used to wait for many dynamically created tasks.

```
sync for i in 1..n do begin work();
```

The for loop is within a sync statement and thus the tasks created in each iteration of the loop must complete before the continuing past the sync statement.

*Example (syncStmt2.chpl)*. The sync statement

```
sync {
    begin stmt1();
    begin stmt2();
}
```

is similar to the following cobegin statement

```
cobegin {
    stmt1();
    stmt2();
}
```

except that if begin statements are dynamically encountered when `stmt1()` or `stmt2()` are executed, then the former code will wait for these begin statements to complete whereas the latter code will not.

24.9 The Serial Statement

The serial statement can be used to dynamically disable parallelism. The syntax is:

\[
\text{serial \text{-} statement:} \\
\text{serial expression\text{-}opt do statement} \\
\text{serial expression\text{-}opt block\text{-}statement}
\]

where the optional expression evaluates to a boolean value. If the expression is omitted, it is as though 'true' were specified. Whatever the expression’s value, the statement following it is evaluated. If the expression is true, any dynamically encountered code that would normally create new tasks within the statement is instead executed by the original task without creating any new ones. In effect, execution is serialized. If the expression is false, code within the statement will generates task according to normal Chapel rules.
Example (serialStmt1.chpl). In the code

```chpl
proc f(i) {
    serial i<13 {
        cobegin {
            work(i);
            work(i);
        }
    }
}
for i in lo..hi {
    f(i);
}
```

the serial statement in procedure f() inhibits concurrent execution of work() if the variable i is less than 13.

Example (serialStmt2.chpl). The code

```chpl
serial {
    begin stmt1();
    cobegin {
        stmt2();
        stmt3();
    }
    coforall i in 1..n do stmt4();
}
```

is equivalent to

```chpl
stmt1();
{
    stmt2();
    stmt3();
}
for i in 1..n do stmt4();
```

because the expression evaluated to determine whether to serialize always evaluates to true.

### 24.10 Atomic Statements

*Open issue.* This section describes a feature that is a work-in-progress. We seek feedback and collaboration in this area from the broader community.

The **atomic statement** is used to specify that a statement should appear to execute atomically from other tasks’ point of view. In particular, no task will see memory in a state that would reflect that the atomic statement had begun executing but had not yet completed.

*Open issue.* This definition of the atomic statement provides a notion of **strong atomicity** since the action will appear atomic to any task at any point in its execution. For performance reasons, it could be more practical to support **weak atomicity** in which the statement’s atomicity is only guaranteed with respect to other atomic statements. We may also pursue using atomic type qualifiers as a means of marking data that should be accessed atomically inside or outside an atomic section.
The syntax for the atomic statement is given by:

```
atomic-statement:
   atomic statement
```

*Example.* The following code illustrates the use of an atomic statement to perform an insertion into a doubly-linked list:

```plaintext
proc Node.insertAfter(newNode: Node) {
    atomic {
        newNode.prev = this;
        newNode.next = this.next;
        if this.next then this.next.prev = newNode;
        this.next = newNode;
    }
}
```

The use of the atomic statement in this routine prevents other tasks from viewing the list in a partially-updated state in which the pointers might not be self-consistent.
25 Data Parallelism

Chapel provides two explicit data-parallel constructs (the forall-statement and the forall-expression) and several idioms that support data parallelism implicitly (whole-array assignment, function and operator promotion, reductions, and scans).

This chapter details data parallelism as follows:

- §25.1 describes the forall statement.
- §25.2 describes forall expressions
- §25.3 specifies how variables from outer scopes are handled within forall statements and expressions.
- §25.4 describes promotion.
- §25.5 describes reductions and scans.
- §25.6 describes the configuration constants for controlling default data parallelism.

25.1 The Forall Statement

The forall statement is a concurrent variant of the for statement described in §11.9.

25.1.1 Syntax

The syntax of the forall statement is given by

```
forall-statement:
    forall index-var-declaration in iterable-expression task-intent-clause_opt do statement
    forall index-var-declaration in iterable-expression task-intent-clause_opt block-statement
    forall iterable-expression task-intent-clause_opt do statement
    forall iterable-expression task-intent-clause_opt block-statement
    [ index-var-declaration in iterable-expression task-intent-clause_opt ] statement
    [ iterable-expression task-intent-clause_opt ] statement
```

As with the for statement, the indices may be omitted if they are unnecessary and the do keyword may be omitted before a block statement. The square bracketed form is a syntactic convenience.

The handling of the outer variables within the forall statement and the role of task-intent-clause are defined in §25.3.
25.1.2 Execution and Serializability

The forall statement evaluates the loop body once for each element yielded by the `iterable-expression`. Each instance of the forall loop’s body may be executed concurrently with the others, but this is not guaranteed. In particular, the loop must be serializable. Details regarding concurrency and iterator implementation are described in §21.4.

This differs from the semantics of the `coforall` loop, discussed in §24.6, where each iteration is guaranteed to run using a distinct task. The `coforall` loop thus has potentially higher overhead than a forall loop with the same number of iterations, but in cases where concurrency is required for correctness, it is essential.

In practice, the number of tasks that will be used to evaluate a `forall` loop is determined by the object or iterator that is leading the execution of the loop, as is the mapping of iterations to tasks.

This concept will be formalized in future drafts of the Chapel specification; for now, please refer to CHPL_HOME/examples/primers/leaderfollower.chpl for a brief introduction or to User-Defined Parallel Zippered Iterators in Chapel, published in the PGAS 2011 workshop.

Control continues with the statement following the forall loop only after every iteration has been completely evaluated. At this point, all data accesses within the body of the forall loop will be guaranteed to be completed.

The following statements may not be lexically enclosed in forall statements: break statements, and return statements. Yield statement may only be lexically enclosed in forall statements in parallel iterators (§21.4).

Example (forallStmt.chpl). In the code

```chapel
forall i in 1..N do
  a(i) = b(i);
```

the user has stated that the element-wise assignments can execute concurrently. This loop may be executed serially with a single task, or by using a distinct task for every iteration, or by using a number of tasks where each task executes a number of iterations. This loop can also be written as

```chapel
[i in 1..N] a(i) = b(i);
```

25.1.3 Zipper Iteration

Zipper iteration has the same semantics as described in §11.9.1 and §21.4 for parallel iteration.

25.2 The Forall Expression

The forall expression is a concurrent variant of the for expression described in §10.21.
25.2.1 Syntax

The syntax of a forall expression is given by

\[
\text{forall-expression:} \\
\quad \text{forall} \quad \text{index-declaration in} \quad \text{iteratable-expression task-intent-clause}\text{opt} \quad \text{do expression} \\
\quad \text{forall} \quad \text{iteratable-expression task-intent-clause}\text{opt} \quad \text{do expression} \\
\quad [ \text{index-declaration in} \quad \text{iteratable-expression task-intent-clause}\text{opt} ] \quad \text{expression} \\
\quad [ \text{iteratable-expression task-intent-clause}\text{opt} ] \quad \text{expression}
\]

As with the for expression, the indices may be omitted if they are unnecessary. The do keyword is always required in the keyword-based notation. The bracketed form is a syntactic convenience.

The handling of the outer variables within the forall expression and the role of task-intent-clause are defined in §25.3.

25.2.2 Execution and Serializability

The forall expression executes a forall loop (§25.1), evaluates the body expression on each iteration of the loop, and returns the resulting values as a collection. The size and shape of that collection are determined by the iteratable-expression.

Example (forallExpr.chpl). The code

\[
\text{writeln}(+ \text{reduce} \ [i \text{ in } 1..10] i^2);
\]

applies a reduction to a forall-expression that evaluates the square of the indices in the range 1..10.

The forall expression follows the semantics of the forall statement as described in §25.1.2.

25.2.3 Zipper Iteration

Forall expression also support zippered iteration semantics as described in §11.9.1 and §21.4 for parallel iteration.

25.2.4 Filtering Predicates in Forall Expressions

A filtering predicate is an if expression that is immediately enclosed by a forall expression and does not have an else clause. Such an if expression filters the iterations of the forall expression. The iterations for which the condition does not hold are not reflected in the result of the forall expression.

Example (forallFilter.chpl). The following expression returns every other element starting with the first:

\[
[i \text{ in } 1..s\text{.numElements}] \text{ if } i \% 2 == 1 \text{ then } s(i)
\]
### 25.3 Forall Intents

If a variable is referenced within the lexical scope of a forall statement or expression and is declared outside that statement or expression, it is subject to *forall intents*, analogously to task intents ([24.7]) for task-parallel constructs. That is, the variable is considered to be passed as an actual argument to each task function created by the object or iterator leading the execution of the loop. If no tasks are created, it is considered to be an actual argument to the leader iterator itself. All references to the variable within the forall statement or expression implicitly refer to the corresponding formal argument of the task function or the leader iterator.

Each formal argument of a task function or iterator has the default intent by default. For variables of primitive, enum, class, record and union types, this has the effect of capturing the value of the variable at task creation time. Within the lexical scope of the forall statement or expression, the variable name references the captured value instead of the original value.

A formal can be given another intent explicitly by listing it with that intent in the optional `task-intent-clause`. For example, for variables of most types, the `ref` intent allows the body of the forall loop to modify the corresponding original variable or to read its updated value after concurrent modifications. The `in` intent is a way to obtain task-private variables in a forall loop.

*Rationale*. A forall statement or expression may create tasks in its implementation. Forall intents affect those tasks in the same way that task intents affect the behavior of a task construct such as a `coforall` loop.

*Cray's Chapel Implementation*. An initial implementation of "reduce" intents is also available, which permits users to reduce values across iterations of a forall loop. They are described in the *Reduce Intents* page under *Technical Notes* in Cray Chapel online documentation here:

### 25.4 Promotion

A function that expects one or more scalar arguments but is called with one or more arrays, domains, ranges, or iterators is promoted if the element types of the arrays, the index types of the domains and/or ranges, or the yielded types of the iterators can be resolved to the type of the argument. The rules of when an overloaded function can be promoted are discussed in [13.12](#).

In addition to scalar functions, operators and casts are also promoted.

*Example (promotion.chpl)*. Given the array

```chapel
var A: [1..5] int = [i in 1..5] i;
```

and the function

```chapel
proc square(x: int) return x**2;
```

then the call `square(A)` results in the promotion of the `square` function over the values in the array `A`. The result is an iterator that returns the values 1, 4, 9, 16, and 25.

Whole array operations are a form of promotion as applied to operators rather than functions.
25.4.1 Zipper Promotion

Promotion also supports zippered iteration semantics as described in §11.9.1 and §21.4 for parallel iteration.

Consider a function $f$ with formal arguments $s_1, s_2, ...$ that are promoted and formal arguments $a_1, a_2, ...$ that are not promoted. The call

$$f(s_1, s_2, ..., a_1, a_2, ...)$$

is equivalent to

$$[(e_1, e_2, ...) \text{ in zip}(s_1, s_2, ...)] f(e_1, e_2, ..., a_1, a_2, ...)$$

The usual constraints of zipper iteration apply to zipper promotion so the promoted actuals must have the same shape.

Example (zipper-promotion.chpl). Given a function defined as

```chpl
proc foo(i: int, j: int) {
  return (i,j);
}
```

and a call to this function written

```chpl
writeln(foo(1..3, 4..6));
```

then the output is

$$(1, 4) (2, 5) (3, 6)$$

25.4.2 Whole Array Assignment

Whole array assignment is considered a degenerate case of promotion and is implicitly parallel. The assignment statement

$$\text{LHS} = \text{RHS};$$

is equivalent to

```chpl
forall (el, e2) in zip(LHS, RHS) do
  el = e2;
```

25.4.3 Evaluation Order

The semantics of whole array assignment and promotion are different from most array programming languages. Specifically, the compiler does not insert array temporaries for such operations if any of the right-hand side array expressions alias the left-hand side expression.

Example. If $A$ is an array declared over the indices $1..5$, then the following codes are not equivalent:

and

```plaintext
```

This follows because, in the former code, some of the new values that are assigned to $A$ may be read to compute the sum depending on the number of tasks used to implement the data parallel statement.

## 25.5 Reductions and Scans

Chapel provides reduction and scan expressions that apply operators to aggregate expressions in stylized ways. Reduction expressions collapse the aggregate’s values down to a summary value. Scan expressions compute an aggregate of results where each result value stores the result of a reduction applied to all of the elements in the aggregate up to that expression. Chapel provides a number of predefined reduction and scan operators, and also supports a mechanism for the user to define additional reductions and scans (Chapter 28).

### 25.5.1 Reduction Expressions

A reduction expression applies a reduction operator to an aggregate expression, collapsing the aggregate’s dimensions down into a result value (typically a scalar or summary expression that is independent of the input aggregate’s size). For example, a sum reduction computes the sum of all the elements in the input aggregate expression.

The syntax for a reduction expression is given by:

```plaintext
reduce-expression:
  reduce–scan–operator reduce iterable–expression
class–type reduce iterable–expression

reduce–scan–operator: one of
  +  *  &&  ||  &  |  ^  min  max  minloc  maxloc
```

Chapel’s predefined reduction operators are defined by `reduce–scan–operator` above. In order, they are: sum, product, logical-and, logical-or, bitwise-and, bitwise-or, bitwise-exclusive-or, minimum, maximum, minimum-with-location, and maximum-with-location. The minimum reduction returns the minimum value as defined by the `<` operator. The maximum reduction returns the maximum value as defined by the `>` operator. The minimum-with-location reduction returns the lowest index position with the minimum value (as defined by the `<` operator). The maximum-with-location reduction returns the lowest index position with the maximum value (as defined by the `>` operator).

The expression on the right-hand side of the `reduce` keyword can be of any type that can be iterated over, provided the reduction operator can be applied to the values yielded by the iteration. For example, the bitwise-and operator can be applied to arrays of boolean or integral types to compute the bitwise-and of all the values in the array.

For the minimum-with-location and maximum-with-location reductions, the argument on the right-hand side of the `reduce` keyword must be a 2-tuple. Its first component is the collection of values for which the minimum/maximum value is to be computed. The second argument component is a collection of indices with the same size and shape that provides names for the locations of the values in the first component. The reduction returns a tuple containing the minimum/maximum value in the first argument component and the value at the corresponding location in the second argument component.
**Example (reduce-loc.chpl).** The first line below computes the smallest element in an array \( A \) as well as its index, storing the results in \( \text{minA} \) and \( \text{minALoc} \), respectively. It then computes the largest element in a forall expression making calls to a function \( \text{foo}() \), storing the value and its number in \( \text{maxVal} \) and \( \text{maxValNum} \).

```chpl
var (minA, minALoc) = minloc reduce zip(A, A.domain);
var (maxVal, maxValNum) = maxloc reduce zip([i in 1..n] foo(i), 1..n);
```

User-defined reductions are specified by preceding the keyword `reduce` by the class type that implements the reduction interface as described in §28.

### 25.5.2 Scan Expressions

A scan expression applies a scan operator to an aggregate expression, resulting in an aggregate expression of the same size and shape. The output values represent the result of the operator applied to all elements up to and including the corresponding element in the input.

The syntax for a scan expression is given by:

```chpl
scan-expression:
reduce-scan-operator scan iterable-expression
class-type scan iterable-expression
```

The predefined scans are defined by `reduce-scan-operator`. These are identical to the predefined reductions and are described in §25.5.1.

The expression on the right-hand side of the scan can be of any type that can be iterated over and to which the operator can be applied.

**Example.** Given an array

```chpl
var A: [1..3] int = 1;
```

that is initialized such that each element contains one, then the code

```chpl
writeln(+ scan A);
```

outputs the results of scanning the array with the sum operator. The output is

```
1 2 3
```

User-defined scans are specified by preceding the keyword `scan` by the class type that implements the scan interface as described in Chapter 28.
25.6 Configuration Constants for Default Data Parallelism

The following configuration constants are provided to control the degree of data parallelism over ranges, default domains, and default arrays:

<table>
<thead>
<tr>
<th>Config Const</th>
<th>Type</th>
<th>Default</th>
</tr>
</thead>
<tbody>
<tr>
<td>dataParTasksPerLocale</td>
<td>int</td>
<td>top level .maxTaskPar (see [26.1.2])</td>
</tr>
<tr>
<td>dataParIgnoreRunningTasks</td>
<td>bool</td>
<td>true</td>
</tr>
<tr>
<td>dataParMinGranularity</td>
<td>int</td>
<td>1</td>
</tr>
</tbody>
</table>

The configuration constant `dataParTasksPerLocale` specifies the number of tasks to use when executing a forall loop over a range, default domain, or default array. The actual number of tasks may be fewer depending on the other two configuration constants. A value of zero results in using the default value.

The configuration constant `dataParIgnoreRunningTasks`, when true, has no effect on the number of tasks to use to execute the forall loop. When false, the number of tasks per locale is decreased by the number of tasks that are already running on the locale, with a minimum value of one.

The configuration constant `dataParMinGranularity` specifies the minimum number of iterations per task created. The number of tasks is decreased so that the number of iterations per task is never less than the specified value.

For distributed domains and arrays that have these same configuration constants (e.g., Block and Cyclic distributions), these same module level configuration constants are used to specify their default behavior within each locale.
26 Locales

Chapel provides high-level abstractions that allow programmers to exploit locality by controlling the affinity of both data and tasks to abstract units of processing and storage capabilities called *locales*. The on-statement allows for the migration of tasks to remote locales.

Throughout this section, the term *local* will be used to describe the locale on which a task is running, the data located on this locale, and any tasks running on this locale. The term *remote* will be used to describe another locale, the data on another locale, and the tasks running on another locale.

26.1 Locales

A *locale* is a portion of the target parallel architecture that has processing and storage capabilities. Chapel implementations should typically define locales for a target architecture such that tasks running within a locale have roughly uniform access to values stored in the locale’s local memory and longer latencies for accessing the memories of other locales. As an example, a cluster of multicore nodes or SMPs would typically define each node to be a locale. In contrast a pure shared memory machine would be defined as a single locale.

26.1.1 Locale Types

The identifier *locale* is a class type that abstracts a locale as described above. Both data and tasks can be associated with a value of locale type. A Chapel implementation may define subclass(es) of *locale* for a richer description of the target architecture.

26.1.2 Locale Methods

The locale type supports the following methods:

```chapel
proc locale.callStackSize: uint(64);

Returns the per-task call stack size used when creating tasks on the locale in question. A value of 0 indicates that the call stack size is determined by the system.
```

```chapel
proc locale.id: int;

Retuns a unique integer for each locale, from 0 to the number of locales less one.
```

```chapel
proc locale.maxTaskPar: int(32);

Returns an estimate of the maximum parallelism available for tasks on a given locale.
```

```chapel
proc locale.name: string;
```

Returns the name of the locale.

\[
\text{proc locale}.\text{numCores}: \text{int};
\]

Returns the number of logical CPUs available on a given locale.

\[
\text{use Memory;}
\]
\[
\text{proc locale}.\text{physicalMemory}(\text{unit: MemUnits=MemUnits.Bytes, type retType=int(64)}): \text{retType};
\]

Returns the amount of physical memory available on a given locale in terms of the specified memory units (Bytes, KB, MB, or GB) using a value of the specified return type.

### 26.1.3 The Predefined Locales Array

Chapel provides a predefined environment that stores information about the locales used during program execution. This execution environment contains definitions for the array of locales on which the program is executing (Locales), a domain for that array (LocaleSpace), and the number of locales (numLocales).

\[
\text{config const numLocales: int;}
\]
\[
\text{const LocaleSpace: domain(1) = [0..numLocales-1];}
\]
\[
\text{const Locales: [LocaleSpace] locale;}
\]

When a Chapel program starts, a single task executes `main` on `Locales(0)`.

Note that the Locales array is typically defined such that distinct elements refer to distinct resources on the target parallel architecture. In particular, the Locales array itself should not be used in an oversubscribed manner in which a single processor resource is represented by multiple locale values (except during development). Oversubscription should instead be handled by creating an aggregate of locale values and referring to it in place of the Locales array.

Rationale. This design choice encourages clarity in the program’s source text and enables more opportunities for optimization.

For development purposes, oversubscription is still very useful and this should be supported by Chapel implementations to allow development on smaller machines.

Example. The code

\[
\text{const MyLocales: [0..numLocales*4] locale}
\]
\[
= [\text{loc in } 0..\text{numLocales*4}] \text{Locales(loc%numLocales)};
\]
\[
\text{on MyLocales[i]} \ldots
\]

defines a new array `MyLocales` that is four times the size of the `Locales` array. Each locale is added to the `MyLocales` array four times in a round-robin fashion.
26.1.4 The here Locale

A predefined constant locale here can be used anywhere in a Chapel program. It refers to the locale that the current task is running on.

*Example.* The code

```chapel
on Locales(1) {
  writeln(here.id);
}
```

results in the output 1 because the writeln statement is executed on locale 1.

The identifier here is not a keyword and can be overridden.

26.1.5 Querying the Locale of an Expression

The locale associated with an expression (where the expression is stored) is queried using the following syntax:

```
locale-access-expression: expression . locale
```

When the expression is a class, the access returns the locale on which the class object exists rather than the reference to the class. If the expression is a value, it is considered local. The implementation may warn about this behavior. If the expression is a locale, it is returned directly.

*Example.* Given a class C and a record R, the code

```chapel
on Locales(1) {
  var x: int;
  var c: C;
  var r: R;
  on Locales(2) {
    on Locales(3) {
      c = new C();
      r = new R();
    } writeln(x.locale.id);
    writeln(c.locale.id);
    writeln(r.locale.id);
  }
}
```

results in the output

```
1
3
1
```

The variable x is declared and exists on Locales(1). The variable c is a class reference. The reference exists on Locales(1) but the object itself exists on Locales(3). The locale access returns the locale where the object exists. Lastly, the variable r is a record and has value semantics. It exists on Locales(1) even though it is assigned a value on a remote locale.
Locales

Global (non-distributed) constants are replicated across all locales.

**Example.** For example, the following code:

```plaintext
const c = 10;
for loc in Locales do on loc do
    writeln(c.locale.id);)
```

outputs

0
1
2
3
4

to when running on 5 locales.

### 26.2 The On Statement

The on statement controls on which locale a block of code should be executed or data should be placed. The syntax of the on statement is given by

- **on-statement:**
  - `on expression do statement`
  - `on expression block-statement`

The locale of the expression is automatically queried as described in §26.1.5 Execution of the statement occurs on this specified locale and then continues after the on-statement.

Return statements may not be lexically enclosed in on statements. Yield statements may only be lexically enclosed in on statements in parallel iterators §21.4

#### 26.2.1 Remote Variable Declarations

By default, when new variables and data objects are created, they are created in the locale where the task is running. Variables can be defined within an on-statement to define them on a particular locale such that the scope of the variables is outside the on-statement. This is accomplished using a similar syntax but omitting the do keyword and braces. The syntax is given by:

- **remote-variable-declaration-statement:**
  - `on expression variable-declaration-statement`
27 Domain Maps

A domain map specifies the implementation of the domains and arrays that are *mapped* using it. That is, it defines how domain indices and array elements are mapped to locales, how they are stored in memory, and how operations such as accesses, iteration, and slicing are performed. Each domain and array is mapped using some domain map.

A domain map is either a *layout* or a *distribution*. A layout describes domains and arrays that exist on a single locale, whereas a distribution describes domains and arrays that are partitioned across multiple locales.

A domain map is represented in the program with an instance of a *domain map class*. Chapel provides a set of standard domain map classes. Users can create domain map classes as well.

Domain maps are presented as follows:

- domain maps for domain types §27.1, domain values §27.2, and arrays §27.3
- domain maps are not retained upon domain assignment §27.4
- standard layouts and distributions, such as Block and Cyclic, are documented under *Standard Library* in Cray Chapel online documentation here:
- specification of user-defined domain maps is forthcoming; please refer to the *Domain Map Standard Interface* page under *Technical Notes* in Cray Chapel online documentation here:

27.1 Domain Maps for Domain Types

Each domain type has a domain map associated with it. This domain map is used to map all domain values of this type (§27.2).

If a domain type does not have a domain map specified for it explicitly as described below, a default domain map is provided by the Chapel implementation. Such a domain map will typically be a layout that maps the entire domain to the locale on which the domain value is created or the domain or array variable is declared.

*Cray’s Chapel Implementation*. The default domain map provided by the Cray Chapel compiler is such a layout. The storage for the representation of a domain’s index set is placed on the locale where the domain variable is declared. The storage for the elements of arrays declared over domains with the default map is placed on the locale where the array variable is declared. Arrays declared over rectangular domains with this default map are laid out in memory in row-major order.

A domain map can be specified explicitly by providing a *dmap value* in a *dmapped* clause:
A dmap value consists of an instance of a domain map class wrapped in an instance of the predefined record dmap. The domain map class is chosen and instantiated by the user. dmap behaves like a generic record with a single generic field, which holds the domain map instance.

**Example.** The code

```chapel
use BlockDist;
var MyBlockDist: dmap(Block(rank=2));
```

declares a variable capable of storing dmap values for a two-dimensional Block distribution. The Block distribution is described in more detail here:

**Example.** The code

```chapel
use BlockDist;
var MyBlockDist: dmap(Block(rank=2)) = new dmap(new Block({1..5,1..6}));
```

creates a dmap value wrapping a two-dimensional Block distribution with a bounding box of \((1..5, 1..6)\) over all of the locales.

**Example.** The code

```chapel
use BlockDist;
var MyBlockDist = new dmap(new Block({1..5,1..6}));
type MyBlockedDom = domain(2) dmapped MyBlockDist;
```

defines a two-dimensional rectangular domain type that is mapped using a Block distribution.

The following syntactic sugar is provided within the dmapped clause. If a dmapped clause starts with the name of a domain map class, it is considered to be a constructor expression as if preceeded by `new`. The resulting domain map instance is wrapped in a newly-created instance of dmap implicitly.

**Example.** The code

```chapel
use BlockDist;
type BlockDom = domain(2) dmapped Block({1..5,1..6});
```

is equivalent to

```chapel
use BlockDist;
type BlockDom = domain(2) dmapped new dmap{new Block({1..5,1..6})};
```
27.2 Domain Maps for Domain Values

A domain value is always mapped using the domain map of that value’s type. The type inferred for a domain literal (§19.2.1) has a default domain map.

*Example.* In the following code

```
use BlockDist;
var MyDomLiteral = {1..2,1..3};
var MyBlockedDom: domain(2) dmapped Block({1..5,1..6}) = MyDomLiteral;
```

MyDomLiteral is given the inferred type of the domain literal and so will be mapped using a default map. MyBlockedDom is given a type explicitly, in accordance to which it will be mapped using a Block distribution.

A domain value’s map can be changed explicitly with a `dmapped` clause, in the same way as a domain type’s map.

*mapped–domain–expression:*

```
domain–expression dmapped dmap–value
```

*Example.* In the following code

```
use BlockDist;
var MyBlockedDomLiteral1 = {1..2,1..3} dmapped new dmap(new Block({1..5,1..6}));
var MyBlockedDomLiteral2 = {1..2,1..3} dmapped Block({1..5,1..6});
```

both MyBlockedDomLiteral1 and MyBlockedDomLiteral2 will be mapped using a Block distribution.

27.3 Domain Maps for Arrays

Each array is mapped using the domain map of the domain over which the array was declared.

*Example.* In the code

```
use BlockDist;
var Dom: domain(2) dmapped Block({1..5,1..6}) = {1..5,1..6};
var MyArray: [Dom] real;
```

the domain map used for MyArray is the Block distribution from the type of Dom.
27.4 Domain Maps Are Not Retained upon Domain Assignment

Domain assignment (§19.8.1) transfers only the index set of the right-hand side expression. The implementation of the left-hand side domain expression, including its domain map, is determined by its type and so does not change upon a domain assignment.

**Example.** In the code

```plaintext
use BlockDist;
var Dom1: domain(2) mapped Block({1..5,1..6}) = {1..5,1..6};
var Dom2: domain(2) = Dom1;
```

`Dom2` is mapped using the default distribution, despite `Dom1` having a Block distribution.

**Example.** In the code

```plaintext
use BlockDist;
var Dom1: domain(2) mapped Block({1..5,1..6}) = {1..5,1..6};
var Dom2 = Dom1;
```

`Dom2` is mapped using the same distribution as `Dom1`. This is because the declaration of `Dom2` lacks an explicit type specifier and so its type is defined to be the type of its initialization expression, `Dom1`. So in this situation the effect is that the domain map does transfer upon an initializing assignment.
User-defined reductions and scans are supported via class definitions where the class implements a structural interface. The definition of this structural interface is forthcoming. The following paper sketched out such an interface:

In this section, we describe Chapel’s memory consistency model. The model is based on sequential consistency for data-race-free programs as adopted by C11, C++11, Java, UPC, and Fortran 2008.

Sequential consistency (SC) means that all Chapel tasks agree on the interleaving of memory operations and this interleaving results in an order consistent with the order of operations in the program source code. Conflicting memory operations, i.e., operations to the same location and one of which is a write, form a data race if they are from different Chapel tasks and can be executed concurrently. Any Chapel program with a data race is not a valid program, and an implementation cannot be relied upon to produce consistent behavior. Valid Chapel programs will use synchronization constructs such as sync, single, or atomic variables or higher-level constructs based on these to enforce ordering for conflicting memory operations.

The following design principles were used in developing Chapel’s memory consistency model:

1. Sequential programs have program order semantics. Programs that are completely sequential cannot have data races and should appear to execute as though each statement was executed one at a time and in the expected order.

2. Chapel’s fork-join constructs introduce additional order dependencies. Operations within a task cannot behave as though they started before the task started. Similarly, all operations in a task must appear to be completed to a parent task when the parent task joins with that task.

3. Multi-locale programs have the same memory consistency model as single-locale programs. The Chapel language seeks to allow a single description of an algorithm to work with different data distributions. A result of this property is that an expression of a program must be correct whether it is working on local or distributed data.

4. Chapel’s memory model should be as relaxed as possible while still consistent with these design principles. In particular, making all operations sequentially consistent is not likely to enable good performance. At the same time, sequential consistency should be available to programmers when requested.

See A Primer on Memory Consistency and Cache Coherence by Sorin, et al. for more background information on memory consistency models. This chapter will proceed in a manner inspired by the XC memory model described there.

**29.1 Sequential Consistency for Data-Race-Free Programs**

Sequential consistency for data-race-free programs is described in terms of two orders: program order and memory order. The program order \( <_p \) is a partial order describing serial or fork-join parallelism dependencies between variable reads and writes. The memory order \( <_m \) is a total order that describes the semantics of synchronizing memory operations (via atomic, sync or single variables) with sequential consistency. Non-SC atomic operations (described in Section \[29.2\]) do not create this total order.
Note that sync/single variables have memory consistency behavior equivalent to a sequence of SC operations on atomic variables. Thus for the remainder of the chapter, we will primarily focus on operations on atomic variables.

We will use the following notation:

- \( L(a) \) indicates a load from a variable at address \( a \). \( a \) could refer to local or remote memory.
- \( S(a) \) indicates a store to a variable at address \( a \). \( a \) could refer to local or remote memory.
- \( A_{sc}(a) \) indicates an atomic operation on a variable at address \( a \) with sequential consistency. The variable at address \( a \) could refer to local or remote memory. Atomic operations must be completed as a single operation (i.e. atomically), and so it is not possible to observe an intermediate state from an atomic operation under any circumstances.
- \( A_r(a, o) \) indicates an atomic operation on a variable at address \( a \) with ordering constraint \( o \), where \( o \) can be one of relaxed, acquire, or release (see Section 29.2). As with \( A_{sc}(a) \), relaxed atomic operations must be completed as a single operation.
- \( L(a) \), \( S(a) \), \( A_{sc}(a) \), and \( A_r(a, o) \) are also called memory operations
- \( X <_p Y \) indicates that \( X \) precedes \( Y \) in program order
- \( X <_m Y \) indicates that \( X \) precedes \( Y \) in memory order
- \( t = \text{begin}(X) \) starts a new task named \( t \) to execute \( X \)
- \( \text{waitFor}(t_1 \ldots t_n) \) waits for tasks \( t_1 \ldots t_n \) to complete
- \( \text{on}(L) \) migrates the running task to locale \( L \). Note that while the on statement may change the locale on which the current task is running, it has no impact on the memory consistency requirements.

For the purposes of describing this memory model, it is assumed that Chapel programs will be translated into sequences of memory operations, begin statements, and waitFor statements. The translation of a Chapel program into a sequence of memory operations must preserve sequential program semantics. That is, if we have a snippet of a Chapel program without task operations, such as \( X; Y \), the statements \( X \) and \( Y \) will be converted into a sequence of load, store, and atomic operations in a manner that preserves the behavior of a this serial portion of the program. That is, \( X = x_1, x_2, \ldots \) and \( Y = y_1, y_2, \ldots \) where \( x_i \) and \( y_j \) are each a sequence of load, store, or atomic operations and we have \( x_i <_p y_j \).

Likewise, for the purposes of this memory model, Chapel’s parallelism keywords are viewed as a sequence of operations including the primitives of starting a task (begin) and waiting for some number of tasks (waitFor(\( t_1 \ldots t_n \))). In particular:

- forall (including promotion) creates some number of tasks \( m \) to execute the \( n \) iterations of the loop (\( t_i = \text{begin}\{\text{some-loop-bodies}\} \) for each task \( i = 1 \ldots m \)) and waits for them to complete (waitFor(\( t_1 \ldots t_m \))). The number of tasks \( m \) is defined by the implementation of the parallel iterator (See Section 21 for details on iterators).
- coforall creates one task per loop iteration (\( t_i = \text{begin}\{\text{loop-body}\} \) for all loop iterations \( i = 1 \ldots n \)) and then waits for them all to complete (waitFor(\( t_1 \ldots t_n \))).
- cobegin creates one task per enclosed statement (\( t_i = \text{begin}\{X_i\} \) for statements \( X_1 \ldots X_n \)) and then waits for them all to complete (waitFor(\( t_1 \ldots t_n \))).
- begin creates a task to execute the enclosed statement (\( t = \text{begin}(X) \)). The sync statement waits for all tasks \( t_i \) created by a begin statement in the dynamic scope of the sync statement that are not within other, nested sync statements (waitFor(\( t_1 \ldots t_n \)) for all \( n \) such tasks).
29.1.1 Program Order

Task creation and task waiting create a conceptual tree of program statements. The task bodies, task creation, and task wait operations create a partial order $\prec_p$ of program statements. For the purposes of this section, the statements in the body of each Chapel task will be implemented in terms of load, store, and atomic operations.

- If we have a program snippet without tasks, such as $X; Y$, where $X$ and $Y$ are memory operations, then $X \prec_p Y$.
- The program $X; \text{begin}(Y); Z; \text{end}$ implies $X \prec_p Y$. However, there is no particular relationship between $Y$ and $Z$ in program order.
- The program $t = \text{begin}(Y); \text{waitFor}(t); Z; \text{end}$ implies $Y \prec_p Z$.
- $X \prec_p Y$ and $Y \prec_p Z$ imply $X \prec_p Z$

29.1.2 Memory Order

The memory order $\prec_m$ of SC atomic operations in a given task respects program order as follows:

- If $A_{sc}(a) \prec_p A_{sc}(b)$ then $A_{sc}(a) \prec_m A_{sc}(b)$

Every SC atomic operation gets its value from the last SC atomic operation before it to the same address in the total order $\prec_m$:

- Value of $A_{sc}(a) = \text{Value of } max_{\prec_m}(A'_{sc}(a) \mid A'_{sc}(a) \prec_m A_{sc}(a))$

For data-race-free programs, every load gets its value from the last store before it to the same address in the total order $\prec_m$:

- Value of $L(a) = \text{Value of } max_{\prec_m}(S(a) \mid S(a) \prec_m L(a) \text{ or } S(a) \prec_p L(a))$

For data-race-free programs, loads and stores are ordered with SC atoms. That is, loads and stores for a given task are in total order $\prec_m$ respecting the following rules which preserve the order of loads and stores relative to SC atomic operations:

- If $L(a) \prec_p A_{sc}(b)$ then $L(a) \prec_m A_{sc}(b)$
- If $S(a) \prec_p A_{sc}(b)$ then $S(a) \prec_m A_{sc}(b)$
- If $A_{sc}(a) \prec_p L(b)$ then $A_{sc}(a) \prec_m L(b)$
- If $A_{sc}(a) \prec_p S(b)$ then $A_{sc}(a) \prec_m S(b)$
For data-race-free programs, loads and stores preserve sequential program behavior. That is, loads and stores to the same address in a given task are in the order \(<_m\) respecting the following rules which preserve sequential program behavior:

- If \(L(a) <_p L'(a)\) then \(L(a) <_m L'(a)\)
- If \(L(a) <_p S(a)\) then \(L(a) <_m S(a)\)
- If \(S(a) <_p S'(a)\) then \(S(a) <_m S'(a)\)

### 29.2 Non-Sequentially Consistent Atomic Operations

Sequential consistency for atomic operations can be a performance bottleneck under some circumstances. Chapel provides non-SC atomic operations to help alleviate such situations. Such uses of atomic operations must be done with care and should generally not be used to synchronize tasks.

Non-SC atomic operations are specified by providing a `memory order` argument to the atomic operations. See Section 24.4.1 for more information on the memory order types.

#### 29.2.1 Relaxed Atomic Operations

Although Chapel’s relaxed atomic operations (`memory_order_relaxed`) do not complete in a total order by themselves and might contribute to non-deterministic programs, relaxed atomic operations cannot contribute to a data race that would prevent sequential consistency.

When relaxed atomics are used only for atomicity and not as part of synchronizing tasks, their effect can be understood in the memory consistency model described in 29.1 by treating them as ordinary loads or stores with two exceptions:

- Atomic operations (including relaxed atomic operations) cannot create data races.
- All atomic operations (including relaxed atomic operations) will eventually be visible to all other threads. This property is not true for normal loads and stores.

### 29.3 Unordered Memory Operations

*Open issue.* Syntax for unordered operations has not yet been finalized.

*Open issue.* Should Chapel provide a memory fence that only completes unordered operations started by the current task?

*Open issue.* Should unordered operations on a particular memory address always wait for the address to be computed?
Open issue. Does starting a task or joining with a task necessarily wait for unordered operations to complete?

Rather than issuing normal loads and stores to read or write local or remote memory, a Chapel program can use unordered loads and stores when preserving sequential program behavior is not important. The following notation for unordered memory operations will be used in this section:

- $UL(a)$ indicates an unordered load from a variable at address $a$. $a$ could point to local or remote memory.
- $US(a)$ indicates an unordered store to a variable at address $a$. Again, $a$ could point to local or remote memory.

The unordered loads and stores $UL(a)$ and $US(a)$ respect fences but not program order. As in Section 29.1.2, unordered loads and stores are ordered with SC atomics. That is, unordered loads and stores for a given task are in total order $<_m$ respecting the following rules which preserve the order of unordered loads and stores relative to SC atomic operations:

- If $UL(a) <_p A_{sc}(b)$ then $UL(a) <_m A_{sc}(b)$
- If $US(a) <_p A_{sc}(b)$ then $US(a) <_m A_{sc}(b)$
- If $A_{sc}(a) <_p UL(b)$ then $A_{sc}(a) <_m UL(b)$
- If $A_{sc}(a) <_p US(b)$ then $A_{sc}(a) <_m US(b)$

Unordered loads and stores do not preserve sequential program behavior.

29.3.1 Unordered Memory Operations Examples

Unordered operations should be thought of as happening in a way that overlaps with the program task. Unordered operations started in different program statements can happen in any order unless an SC atomic operation orders them.

Since unordered operations started by a single task can happen in any order, totally sequential programs can have a data race when using unordered operations. This follows from our original definition of data race.

```chapel
var x: int = 0;
unordered_store(x, 10);
unordered_store(x, 20);
writeln(x);
```

The value of $x$ at the end of this program could be 0, 10, or 20. As a result, programs using unordered loads and stores are not sequentially consistent unless the program can guarantee that unordered operations can never operate on the same memory at the same time when one of them is a store. In particular, the following are safe:

- Unordered stores to disjoint regions of memory.
- Unordered loads from potentially overlapping regions of memory when no store could overlap with the loads.
Unordered loads and stores to the same memory location when these are always separated by an SC atomic operation.

Unordered loads and stores are available as a performance optimization. For example, a program computing a permutation on an array might want to move data between two arrays without requiring any ordering:

```plaintext
cost n = 10;
// P is a permutation on 1..n, in this case reversing its input
var P = for i in 1..n by -1 do i;
// A is an array to permute
var A = for i in 1..n do i;
// Compute, in B, the permutation applied to A
var B: [1..n] int;

for i in 1..n {
  unordered_store(B[P[i]], A[i]);
}
```

### 29.4 Examples

**Example.** In this example, a synchronization variable is used to (a) ensure that all writes to an array of unsynchronized variables are complete, (b) signal that fact to a second task, and (c) pass along the number of values that are valid for reading.

The program

```plaintext
var A: [1..100] real;
var done$: sync int; // initially empty
cobegin |
  // Reader task
  const numToRead = done$; // block until writes are complete
  for i in 1..numToRead do
    writeln("A[", i, "] = ", A[i]);
|
  // Writer task
  const numToWrite = 14; // an arbitrary number
  for i in 1..numToWrite do
    A[i] = i/10.0;
  done$ = numToWrite; // fence writes to A and signal done
|
```

produces the output

```
A[1] = 0.1
A[2] = 0.2
A[3] = 0.3
A[4] = 0.4
A[5] = 0.5
A[6] = 0.6
A[7] = 0.7
A[8] = 0.8
A[9] = 0.9
A[10] = 1.0
A[12] = 1.2
A[14] = 1.4
```
Example (syncSpinWait.chpl). One consequence of Chapel’s memory consistency model is that a task cannot spin-wait on a normal variable waiting for another task to write to that variable. The behavior of the following code is undefined:

```chapel
var x: int;
cobegin with (ref x) {
    while x != 1 do; // INCORRECT spin wait
    x = 1;
}
```

In contrast, spinning on a synchronization variable has well-defined behavior:

```chapel
var x$: sync int;
cobegin {
    while x$.readXX() != 1 do; // spin wait
    x$.writeXF(1);
}
```

In this code, the first statement in the cobegin statement executes a loop until the variable is set to one. The second statement in the cobegin statement sets the variable to one. Neither of these statements block.

Example (atomicSpinWait.chpl). Atomic variables provide an alternative means to spin-wait. For example:

```chapel
var x: atomic int;
cobegin {
    while x.read() != 1 do; // spin wait - monopolizes processor
    x.write(1);
}
```

Example (atomicWaitFor.chpl). The main drawback of the above example is that it prevents the thread executing the spin wait from doing other useful work. Atomic variables include a waitFor method that will block the calling thread until a read of the atomic value matches a particular value. In contrast to the spin wait loop above, waitFor will allow other tasks to be scheduled. For example:

```chapel
var x: atomic int;
cobegin {
    x.waitFor(1);
    x.write(1);
}
```

Future. Upon completion, Chapel’s atomic statement (§24.10) will serve as an additional means of correctly synchronizing between tasks.
Chapel’s interoperability features support cooperation between Chapel and other languages. They provide the ability to create software systems that incorporate both Chapel and non-Chapel components. Thus, they support the reuse of existing software components while leveraging the unique features of the Chapel language.

Interoperability can be broken down in terms of the exchange of types, variables and procedures, and whether these are imported or exported. An overview of procedure importing and exporting is provided in §30.1. Details on sharing types, variables and procedures are supplied in §30.2.

*Future.*

At present, the backend language for Chapel is C, which makes it relatively easy to call C libraries from Chapel and vice versa. To support a variety of platforms without requiring recompilation, it may be desirable to move to an intermediate-language model.

In that case, each supported platform must minimally support that virtual machine. However, in addition to increased portability, a virtual machine model may expose elements of the underlying machine’s programming model (hardware task queues, automated garbage collection, etc.) that are not easily rendered in C. In addition, the virtual machine model can support run-time task migration.

The remainder of this chapter documents Chapel support of interoperability through the existing C-language backend.

### 30.1 Interoperability Overview

The following two subsections provide an overview of calling externally-defined (C) routines in Chapel, and setting up Chapel routines so they can be called from external (C) code.

#### 30.1.1 Calling External Functions

To use an external function in a Chapel program, it is necessary to inform the Chapel compiler of that routine’s signature through an external function declaration. This permits Chapel to bind calls to that function signature during function resolution. The user must also supply a definition for the referenced function by naming a C source file, an object file or an object library on the `chpl` command line.

An external procedure declaration has the following syntax:

```
external–procedure–declaration–statement:
extern external–name_opt proc function–name argument–list return–intent_opt return–type_opt
```
Interoperability

Chapel will call the external function using the parameter types supplied in the `extern` declaration. Therefore, in general, the type of each argument in the supplied argument-list must be the Chapel equivalent of the corresponding external type.

The return value of the function can be used by Chapel only if its type is declared using the optional `return-type` specifier. If it is omitted, Chapel assumes that no value is returned, or equivalently that the function returns `void`.

At present, external iterators are not supported.

Future. The overloading of function names is also not supported directly in the compiler. However, one can use the `external-name` syntax to supply a name to be used by the linker. In this way, function overloading can be implemented “by hand”. This syntax also supports calling external C++ routines: The `external-name` to use is the mangled function name generated by the external compilation environment.

Future. Dynamic dispatch (polymorphism) is also unsupported in this version. But this is not ruled out in future versions. Since Chapel already supports type-based procedure declaration and resolution, it is a small step to translate a type-relative extern method declaration into a virtual method table entry. The mangled name of the correct external function must be supplied for each polymorphic type available. However, most likely the generation of `.chpl` header files from C and C++ libraries can be fully automated.

There are three ways to supply to the Chapel compiler the definition of an external function: as a C source file (.c or .h), as an object file and as an object library. It is platform-dependent whether static libraries (archives), dynamic libraries or both are supported. See the `chpl` man page for more information on how these file types are handled.

### 30.1.2 Calling Chapel Functions

To call a Chapel procedure from external code, it is necessary to expose the corresponding function symbol to the linker. This is done by adding the `export` linkage specifier to the function definition. The `export` specifier ensures that the corresponding procedure will be resolved, even if it is not called within the Chapel program or library being compiled.

An exported procedure declaration has the following syntax:

```chapel
exported-procedure-declaration-statement:
  export external-name_opt proc function-name argument-list return-intent_opt return-type_opt
    function-body

external-name:
  identifier
  string-literal
```

If the optional `external-name` is supplied, then it is used verbatim as the exported function symbol. Otherwise, the Chapel name of the procedure is exported. The rest of the procedure declaration is the same as for a non-exported function. An exported procedure can be called from within Chapel as well. Currently, iterators cannot be exported.

---

1 In UNIX-like programming environments, `nm` and `grep` can be used to find the mangled name of a given function within an object file or object library.
Interoperability

Future. Currently, exported functions cannot have generic, \texttt{param} or type arguments. This is because such functions actually represent a family of functions, specific versions of which are instantiated as need during function resolution.

Instantiating all possible versions of a template function is not practical in general. However, if explicit instantiation were supported in Chapel, an explicit instantiation with the export linkage specifier would clearly indicate that the matching template function was to be instantiated with the given \texttt{param} values and argument types.

30.2 Shared Language Elements

This section provides details on how to share Chapel types, variables and procedures with external code. It is written assuming that the intermediate language is C.

30.2.1 Shared Types

This subsection discusses how specific types are shared between Chapel and external code.

Referring to Standard C Types

In Chapel code, all standard C types must be expressed in terms of their Chapel equivalents. This is true, whether the entity is exported, imported or private. Standard C types and their corresponding Chapel types are shown in the following table.

<table>
<thead>
<tr>
<th>C Type</th>
<th>Chapel Type</th>
<th>C Type</th>
<th>Chapel Type</th>
<th>C Type</th>
<th>Chapel Type</th>
</tr>
</thead>
<tbody>
<tr>
<td>int8_t</td>
<td>int(8)</td>
<td>uint8_t</td>
<td>uint(8)</td>
<td>_real32</td>
<td>real(32)</td>
</tr>
<tr>
<td>int16_t</td>
<td>int(16)</td>
<td>uint16_t</td>
<td>uint(16)</td>
<td>_real64</td>
<td>real(64)</td>
</tr>
<tr>
<td>int32_t</td>
<td>int(32)</td>
<td>uint32_t</td>
<td>uint(32)</td>
<td>_imag32</td>
<td>imag(32)</td>
</tr>
<tr>
<td>int64_t</td>
<td>int(64)</td>
<td>uint64_t</td>
<td>uint(64)</td>
<td>_imag64</td>
<td>imag(64)</td>
</tr>
<tr>
<td>chpl_bool</td>
<td>bool</td>
<td>const char*</td>
<td>c_string</td>
<td></td>
<td></td>
</tr>
<tr>
<td>complex64</td>
<td>complex(64)</td>
<td>complex128</td>
<td>complex(128)</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Standard C types are built-in. Their Chapel equivalents do not have to be declared using the \texttt{extern} keyword.

In C, the “colloquial” integer type names \texttt{char}, \texttt{signed char}, \texttt{unsigned char}, \texttt{(signed) short (int)}, \texttt{unsigned short (int)}, \texttt{(signed) int}, \texttt{unsigned int}, \texttt{(signed) long (int)}, \texttt{unsigned long (int)}, \texttt{(signed) long long (int)}, and \texttt{unsigned long long (int)} may have an implementation-defined width.\footnote{However, most implementations have settled on using 8, 16, 32, and 64 bits (respectively) to represent \texttt{char}, \texttt{short}, \texttt{int} and \texttt{long}, and \texttt{long long} types.} When referring to C types in a Chapel program, the burden of making sure the type sizes agree is on the user. A Chapel implementation must ensure that all of the C equivalents in the above table are defined and have the correct representation with respect to the corresponding Chapel type.
**Referring to External C Types**

An externally-defined type can be referenced using an external type declaration with the following syntax.

```
external-type-alias-declaration-statement:
  extern type type-alias-declaration-list ;
```

In each `type-alias-declaration`, if the `type-specifier` part is supplied, then Chapel uses the supplied type specifier internally. Otherwise, it treats the named type as an opaque type. The definition for an external type must be supplied by a C header file named on the `chpl` command line.

Fixed-size C array types can be described within Chapel using its homogenous tuple type. For example, the C `typedef` `typedef double vec[3];`

can be described in Chapel using

```
extern type vec = 3*real(64);
```

**Referring to External C Structs**

External C struct types can be referred to within Chapel by prefixing a Chapel `record` definition with the `extern` keyword.

```
external-record-declaration-statement:
  extern external-name_opt simple-record-declaration-statement
```

For example, consider an external C structure defined in `foo.h` called `fltdbl`.

```
typedef struct _fltdbl {
  float x;
  double y;
} fltdbl;
```

This type could be referred to within a Chapel program using

```
extern record fltdbl {
  var x: real(32);
  var y: real(64);
}
```

and defined by supplying `foo.h` on the `chpl` command line.

Within the Chapel declaration, some or all of the fields from the C structure may be omitted. The order of these fields need not match the order they were specified within the C code. Any fields that are not specified (or that cannot be specified because there is no equivalent Chapel type) cannot be referenced within the Chapel code. Some effort is made to preserve the values of the undefined fields when copying these structs but Chapel cannot guarantee the contents or memory story of fields of which it has no knowledge.

If the optional `external-name` is supplied, then it is used verbatim as the exported struct symbol.

A C header file containing the struct’s definition in C must be specified on the `chpl` compiler command line. Note that only typedef’d C structures are supported by default. That is, in the C header file, the `struct` must be supplied with a type name through a `typedef` declaration. If this is not true, you can use the `external-name` part to apply the `struct` specifier. As an example of this, given a C declaration of:
Interoperability

```c
struct Vec3 {
    double x, y, z;
};
```
in Chapel you would refer to this struct via

```chapel
extern "struct Vec3" record Vec3 {
    var x, y, z: real(64);
}
```

### Referring to External Structs Through Pointers

An external type which is a pointer to a struct can be referred to from Chapel using an external class declaration. External class declarations have the following syntax.

```
external-class-declaration-statement:
    extern external-nameopt simple-class-declaration-statement
```

External class declarations are similar to external record declarations as discussed above, but place additional requirements on the C code.

For example, given the declaration

```chapel
extern class D {
    var x: real;
}
```
the requirements on the corresponding C code are:

1. There must be a struct type that is typedef’d to have the name _D.
2. A pointer-to-_D type must be typedef’d to have the name D.
3. The _D struct type must contain a field named x of type double.

Like external records/structs, it may also contain other fields that will simply be ignored by the Chapel compiler.

The following C typedef would fulfill the external Chapel class declaration shown above:

```c
typedef struct __D {
    double x;
    int y;
} _D, *D;
```

where the Chapel compiler would not know about the `y` field and therefore could not refer to it or manipulate it.

If the optional `external-name` is supplied, then it is used verbatim as the exported class symbol.
**Opaque Types**

It is possible to refer to external pointer-based C types that cannot be described in Chapel by using the “opaque” keyword. As the name implies, these types are opaque as far as Chapel is concerned and cannot be used for operations other than argument passing and assignment.

For example, Chapel could be used to call an external C function that returns a pointer to a structure (that can’t or won’t be described as an external class) as follows:

```chapel
extern proc returnStructPtr(): opaque;
var structPtr: opaque = returnStructPtr();
```

However, because the type of `structPtr` is opaque, it can be used only in assignments and the arguments of functions expecting the same underlying type.

```chapel
var copyOfStructPtr = structPtr;
extern proc operateOnStructPtr(ptr: opaque);
operateOnStructPtr(structPtr);
```

Like a `void*` in C, Chapel’s `opaque` carries no information regarding the underlying type. It therefore subverts type safety, and should be used with caution.

### 30.2.2 Shared Data

This subsection discusses how to access external variables and constants.

A C variable or constant can be referred to within Chapel by prefixing its declaration with the `extern` keyword. For example:

```chapel
extern var bar: foo;
```

would tell the Chapel compiler about an external C variable named `bar` of type `foo`. Similarly,

```chapel
extern const baz: int(32);
```

would refer to an external 32-bit integer constant named `baz` in the C code. In practice, external consts can be used to provide Chapel definitions for `#defines` and enum symbols in addition to traditional C constants.

*Cray’s Chapel Implementation.* Note that since params must be known to Chapel at compile-time (and because the Chapel compiler doesn’t have the ability to parse C code), external params are not supported.

### 30.2.3 Shared Procedures

This subsection provides additional detail and examples for calling external procedures from Chapel and for exporting Chapel functions for external use.
Calling External C Functions

To call an external C function, a prototype of the routine must appear in the Chapel code. This is accomplished by providing the Chapel signature of the function preceded by the `extern` keyword. For example, for a C function `foo()` that takes no arguments and returns nothing, the prototype would be:

```
extern proc foo();
```

To refer to the return value of a C function, its type must be supplied through a `return-type` clause in the prototype.

If the above function returns a C `double`, it would be declared as:

```
extern proc foo(): real;
```

Similarly, for external functions that expect arguments, the types of those arguments types may be declared in Chapel using explicit argument type specifiers.

The types of function arguments may be omitted from the external procedure declaration, in which case they are inferred based on the Chapel callsite. For example, the Chapel code

```
extern proc foo(x: int, y): real;
var a, b: int;
foo(a, b);
```

would imply that the external function `foo` takes two 64-bit integer values and returns a 64-bit real. External function declarations with omitted type arguments can also be used call external C macros.

External function arguments can be declared using the `default-expression` syntax. In this case, the default argument will be supplied by the Chapel compiler if the corresponding actual argument is omitted at the callsite. For example:

```
extern proc foo(x: int, y = 1.2): real;
foo(0);
```

Would cause external function `foo()` to be invoked with the arguments 0 and 1.2.

C `varargs` functions can be declared using Chapel’s `variable-argument-expression` syntax (`...`). For example, the C `printf` function can be declared in Chapel as

```
extern proc printf(fmt: c_string, vals...?numvals): int;
```

External C functions or macros that accept type arguments can also be prototyped in Chapel by declaring the argument as a type. For example:

```
extern foo(type t);
```

Calling such a routine with a Chapel type will cause the type identifier (e.g., `int`) to be passed to the routine.

---

3 The return type cannot be inferred, since an `extern` procedure declaration has no body.

4 In practice, this will typically only be useful if the external function is a macro or built-in that can handle type identifiers.
30.2.4 Calling Chapel Procedures Externally

To call a Chapel procedure from external code, the procedure name must be exported using the `export` keyword. An exported procedure taking no arguments and returning void can be declared as:

```chapel
export proc foo();
```

If the procedure body is omitted, the procedure declaration is a prototype; the body of the procedure must be supplied elsewhere. In a prototype, the return type must be declared; otherwise, it is assumed to be `void`. If the body is supplied, the return type of the exported procedure is inferred from the type of its return expression(s).

If the optional `external-name` is supplied, that is the name used in linking with external code. For example, if we declare

```chapel
export "myModule_foo" proc foo();
```

then the name `foo` is used to refer to the procedure within chapel code, whereas a call to the same function from C code would appear as `myModule_foo();`. If the external name is omitted, then its internal name is also used externally.

When a procedure is exported, all of the types and functions on which it depends are also exported. Iterators cannot be explicitly exported. However, they are inlined in Chapel code which uses them, so they are exported in effect.

30.2.5 Argument Passing

The manner in which arguments are passed to an external function can be controlled using argument intents. The following table shows the correspondence between Chapel intents and C argument type declarations. These correspondences pertain to both imported and exported function signatures.

<table>
<thead>
<tr>
<th>Chapel</th>
<th>C</th>
</tr>
</thead>
<tbody>
<tr>
<td>T const T</td>
<td>T</td>
</tr>
<tr>
<td>in T</td>
<td>T</td>
</tr>
<tr>
<td>inout T</td>
<td>T*</td>
</tr>
<tr>
<td>out T</td>
<td>T*</td>
</tr>
<tr>
<td>ref T</td>
<td>T*</td>
</tr>
<tr>
<td>param</td>
<td>type char*</td>
</tr>
</tbody>
</table>

Currently, `param` arguments are not allowed in an extern function declaration, and `type` args are passed as a string containing the name of the actual type being passed. Note that the level of indirection is changed when passing arguments to a C function using `inout`, `out`, or `ref` intent. The C code implementing that function must dereference the argument to extract its value.
A  Collected Lexical and Syntax Productions

This appendix collects the syntax productions listed throughout the specification. There are no new syntax productions in this appendix. The productions are listed both alphabetically and in depth-first order for convenience.

A.1  Alphabetical Lexical Productions

binary-digit: one of
    0 1

binary-digits:
    binary-digit
    binary-digit binary-digits

bool-literal: one of
    true false
